Abdominal tenderness, hepatitis and toxemia, fever, headache, myalgia, dysentery, weight loss, leukocytosis and eosinophilia are characteristic of intestinal schistosomiasis. A macrocytic hypochromic anemia and an increased erythrocyte sedimentation rate are often present. Liver function tests are altered and blood gamma globulin is increased. The acute stage lasts three to four months and of course it more severe in heavy infections and in *S. japonicum* infections because of the larger number of eggs produced by this species.

The chronic stage of the disease may develop in eighteen months in heavy infections and as late as twenty-five years in light *S. mansoni* infections. The numerous eggs in transit through the intestinal wall and those trapped in it produce multiple foci of inflammatory reaction with pseudo-tubercle formation, abscesses and ulceration. These chronic inflammatory changes gradually lead to fibrosis. Eggs become imbedded in the appendix and may cause appendicitis. The deposition of eggs in the liver likewise produces an inflammatory reaction in the form of multiple small abscesses and pseudotubercles.

The liver is enlarged in the acute stage of the disease but as the infection becomes chronic the liver recedes in size and although usually slightly enlarged may become subnormal in size. The liver cells are atrophied and there is periportal cirrhosis. Although the cirrhosis of the liver may be extreme especially in *S. japonicum* infections, interference with bile flow rarely occurs. Marked ascites may develop and dilated abdominal thoracic and esophageal veins are often present. The cephalin-cholesterol flocculation test may become significantly positive early in the infection and as the disease progresses this test is usually positive. The thymol turbidity test is also positive especially late in the disease. The spleen enlarges because of the tissue reaction to the eggs to pigment and to portal passive congestion.

Depending upon the intensity and duration of the chronic infection the patient may have a colitis of varying degrees with the formation of polyps. Headache, malaise, irregular slight fever, diarrhea and abdominal pain are common. The appetite becomes poor and the patient loses weight. Leukopenia develops with anemia and the eosinophilia often persists but is not as marked as during the acute stage of the disease. There is a drop in the erythrocyte sedimentation rate. This stage may be prolonged for years and the patient may die of pneumonia or other infections or rupture of esophageal varices.

Eggs occasionally pass into the systemic circulation and are filtered out in the brain or spinal cord producing various nervous disorders. The symptoms encountered are headache, disorientation, coma, aphasia, amnesia, confusion, paraplegia, spasticity, altered reflexes, incontinence, cranial nerve involvement and jacksonian epilepsy.

Secondary pulmonary schistosomiasis due to embolic eggs and occasionally adult worms in the lungs is very common although not usually serious. Dyspnea and moist rales may be present. Heavily infected patients may show signs of pulmonary hypertension and cardiac insufficiency.

There appears to be little or no relationship of schistosomiasis to malignancy of the intestine or liver. Carcinoma of the intestine has been ascribed to *S. japonicum* but data on its relative prevalence in endemic and uninfected areas are not available. Papillomatous and benign tumors are not uncommon among patients with intestinal schistosomiasis.

**Diagnosis.** Patients from an endemic area with a history of intestinal disease, hepatic

**Treatment** No effective specific therapy is available at present. Emetine hydrochloride 0.065 gm intramuscularly daily for twelve days temporarily reduces the egg production of the worms. Sulfonamide administered concurrently appears to be of value. Tartar emetic as given for schistosomiasis temporarily relieves pulmonary symptoms.

Recently Chung and Hou reported clinical and parasitological cures with chloroquine which was administered over a period of 93 to 231 days. The total dosage employed varied from 26.8 to 85.7 gm.

Infections of the brain can be cured only by surgery.

**Prevention** The prevention of pulmonary paragonimiasis consists in eating only thoroughly cooked crayfish and crabs. Salting, pickling or soaking in rice wine is not sufficient to kill the metacercariae. Infected sputum and feces must be disinfected or kept from water.

## Schistosomiasis

### (Bilharziasis)

**Etiology** Schistosomiasis is a chronic disease caused by the eggs and the adult schistosomes or blood flukes. *Schistosoma mansoni* and *S. japonicum* live in the small venules of the intestine and *S. haematobium* in the vesical and pelvic plexuses. The migration of the eggs through the intestine and urinary bladder and their accumulation in the liver, lungs and central nervous system produce the characteristic syndrome.

**Life Cycle** The delicate adult worms which are 0.6 to 2.5 cm in length reside in pairs the female lying in the gynecophoric canal of the male. Depending upon the species of worm from 300 to 3500 eggs are passed daily into the venules. A larval form, miracidium, develops within the egg. Its lytic enzymes and the contraction of the venule rupture the wall of the venule liberating the egg into the perivascular tissues of the intestine or

urinary bladder. The eggs effect a passage into the lumen of these organs and are evacuated in the feces or the urine. On contact with fresh water the miracidia hatch from the eggs and swim about until they find an appropriate snail which they penetrate. After two generations of development and multiplication within the snail the forked tailed cercarial progeny emerge. During bathing swimming or working or washing clothes the skin of man comes in contact with free swimming cercariae which become attached and burrow down to the peripheral capillary bed as the surface film of water drains off. If ingested with water the cercariae penetrate the mucous membrane of the mouth and throat. The cercariae are transported through the afferent blood to the right heart and lungs. They squeeze through the pulmonary capillaries and are carried into the systemic circulation. Usually only those which get into the mesenteric arteries and pass through to the portal vessels survive. Within the intrahepatic portion of the portal system the successful blood fluke larvae feed and rapidly grow. Approximately 20 days after skin exposure the adolescent worms migrate against the portal blood flow into the mesenteric vesical and pelvic venules.

**Geographical Distribution** *S. mansoni* has an extensive distribution in Egypt, Africa, Madagascar, Yemen, the West Indies and the northern part of South America. *S. japonicum* is found in Central and South China, Japan, the Philippines and Celebes. It is found in domestic and wild mammals in Taiwan but the strain does not develop to maturity in man. *S. haematobium* is very prevalent in Egypt and throughout Africa. It is present in areas of the Near East, Middle East, Madagascar, Portugal and a small area near Bombay, India. It is estimated that 114,000,000 persons are infected with schistosomes. Next to malaria it is man's most serious parasitic infection.

## INTESTINAL SCHISTOSOMIASIS

**Symptoms** Intestinal schistosomiasis is caused either by *S. mansoni* which lives primarily in the venules of the large intestine and to a lesser extent in those of the ileum or by *S. japonicum* which inhabits the venules of the small intestine and also the large intestine. The interval between infection and the onset of the acute, generalized symptoms is approximately forty days in *S. mansoni* infections and twenty-eight to thirty-five days in *S. japonicum* infections. Eggs first appear in the stool at about the same time. Symptoms may be absent, very mild or may not appear for years in light infections in which there are relatively few eggs produced to injure the host. The adults live up to twenty-five years.

The infection may be divided clinically into three stages: (1) incubational, the period of migration and maturation of the growing worms; (2) acute, the period of egg laying and the escape of eggs into the lumen of the intestine and bladder; (3) chronic, the period of tissue fibrosis when eggs are trapped in the tissues.

The incubation period is initiated by the

surfaces become inflamed painful micturition and frequency begin and mucus and pus are found in the urine. Daily temperature elevation sweating malaise weakness and dull pain in the suprapubic region occur. The leukocyte count is increased and there is usually a marked eosinophilia. There is a progressive cystitis with ascending secondary infection of the ureters and kidneys and hydronephrosis. Urinary fistulas of the scrotum perineum and adjacent areas are common. A few patients show intestinal and rectal involvement. Liver involvement although not less frequent is much less severe than in *S. japonicum* and *S. mansoni* infection. Pulmonary schistosomiasis however is not uncommon and the presence of the eggs produces parenchymatous and arterial lesions. Extensive vascular arteritis and obliteration may cause death from cardiac failure. Death however is usually due to anemia emaciation exhaustion or secondary infection. Vesical carcinoma is common in Egypt where schistosomiasis haematobium is highly endemic. There appears to be a causal relationship since epithelioma is several times more frequent in patients with vesical schistosomiasis than in uninfected persons. The malignancy occurs relatively early in life and is reported in persons in the ten to twenty-year age group the majority being less than forty years of age.

Autopsy of a series of patients harboring *S. haematobium* revealed eggs in the following organs: urinary bladder 80 per cent, ureters 69 per cent, kidney 46 per cent, vagina 81 per cent, cervix 75 per cent, uterus 79 per cent, fallopian tubes 12 per cent, ovaries 67 per cent, prostate 55 per cent, testes 34 per cent, liver 43 per cent, gall bladder 38 per cent, pancreas 35 per cent, stomach 32 per cent, small intestine 34 per cent, cecum 54 per cent, appendix 60 per cent, ascending colon 66 per cent, transverse colon 73 per cent, descending colon 65 per cent, rectum 75 per cent, supra-renal gland 26 per cent, mesenteric lymph nodes 32 per cent, spleen 34 per cent.

When large numbers of eggs are deposited in these various organs and tissues symptoms may be produced.

**Diagnosis.** Hematuria cystitis urinary calculi and other vesical symptoms in a patient from an endemic area are suggestive. Specific diagnosis consists in the recovery of eggs from the sediment which settles out at the bottom of a urinalysis glass into which the patient has voided. Eggs will also be found in the stool if an intestinal infection is present. Cystoscopic papules sandy patches and papillomata. Biopsy specimens of these areas will con-

tain eggs. Roentgenographic examination will demonstrate calcified areas or shadows when large numbers of eggs have become calcified in the tissues. Intravenous pyelography is useful in demonstrating complications.

**Prognosis.** The prognosis of vesical schistosomiasis is good except in the late ulcerative stages because *S. haematobium* is relatively susceptible to chemotherapy. Patients with chronic severe infections and superimposed septic infections especially the old and debilitated have a poor prognosis.

**Treatment.** Treatment consists in the administration of antimony compounds as recommended for intestinal schistosomiasis. Intensive intravenous therapy employing relatively large amounts of sodium antimony tartrate over a period of forty-eight hours is effective. However the frequency of severe toxic reactions limits the usefulness of this therapeutic regimen. The thioxanthone Miracid D or Nilodin administered orally has been used in *S. haematobium* infections with considerable success. As it acts chiefly upon the reproductive organs of the parasite apparently cured patients frequently relapse. Antibiotics are indicated for secondary bacterial infection.

**Prevention.** Sanitary disposal of human feces and urine is essential for the control of schistosomiasis. The economic need for night soil for fertilizer in the Orient and the religious practice of ablution in Moslem countries are complicating factors. Populations must be educated to use sanitary toilet facilities and to avoid contact with infected water. Safe facilities for bathing and washing of clothes must be provided. Control of snails with copper sulfate sodium pentachlorophenate and dinitro-o-cyclohexylphenol has been extensively used. Migration of snails from nontreated areas into treated areas complicates this method of control. The control of *S. japonicum* is especially difficult because several domestic and wild mammals are natural reservoirs of the infection. Until a cheap nontoxic effective preferably oral chemotherapeutic agent is developed mass treatment cannot be attempted with any expectation of success.

involvement ascites splenomegaly and eosinophilia should be suspected of having schistosomiasis. Late in the disease there is evidence of liver cell damage and the cephalin cholesterol flocculation test, thymol turbidity test and urine urobilinogen test become significantly positive. The specific diagnosis is based upon finding the eggs in the feces. *S. mansoni* with a large lateral spine, *S. haematobium* with a terminal spine and *S. japonicum* with a rudimentary lateral spine. Eggs are not present during the incubationary period, are present in numbers during the acute stage and may become few in numbers as the chronic stage progresses. *S. mansoni* eggs are also found in the urine in a small percentage of the infections. As the infection may be light and the symptoms are not specifically diagnostic, stool examination of all patients from endemic areas is indicated. If the simple smear examination is negative, concentration of the stool by sedimentation or the acid ether technique is required. Proctoscopic examination may reveal small ulcerations or granulomatous nodules and snips of mucosa from these and even normal appearing mucosa of Houston's valve have a high diagnostic value. These mucosal snips unfixed and unstained should be immersed in distilled water for five minutes, pressed between two glass microscope slides and examined for eggs under the low power of the microscope. Occasionally when eggs cannot be found in the feces or rectal mucosa, a liver biopsy may reveal the presence of eggs. Various serological and intradermal tests are useful though not widely available.

**Prognosis.** The prognosis is good in early, light and moderate infections provided that specific therapy is given. Chronic infections and heavy infections usually have severe, extensive hepatic and intestinal damage and in these circumstances the prognosis even with therapy is relatively poor.

**Treatment.** Nutritional therapy and correction of anemia are indicated and the patient should be brought to a satisfactory physical state before being subjected to the rigors of chemotherapy. Vascular shunts, splenectomy and other surgical procedures may be indicated when hepatic damage is extensive. The purpose of specific chemotherapy is to kill the adult worms in order to prevent the formation of toxins and the production of additional eggs. Trivalent antimony compounds, tartar emetic (potassium antimony tartrate), Triostam (sodium antimonyl gluconate) and stibophen (Fua-

din) are the drugs of choice. Stibophen though less effective than tartar emetic is less toxic and is therefore preferred by many. Tartar emetic is slowly administered intravenously as a 0.5 per cent solution as follows: first day 8 ml, third day 12 ml, fifth day 16 ml, seventh day 20 ml, ninth day 24 ml and on alternate days through the twenty-ninth day 28 ml (total 360 ml containing 0.648 gm of antimony).

Stibophen is given intramuscularly as a 6.3 per cent solution. The course of treatment for adults consists of 20 injections of 5 ml on alternate days, starting with 15 ml and 3.5 ml on the first two injections. Children are given a total dose of 1.0 ml per pound of weight in 20 injections. Relapses occur not infrequently so repeated stool examinations should be made several months after the completion of therapy and a second course of treatment given if indicated. Miracid D, a thiovanthone which has the advantage of oral administration, is ineffective against *S. japonicum* and its value in *S. mansoni* infection is questionable but still under investigation.

#### VESICAL SCHISTOSOMIASIS

*Schistosoma haematobium* is the common cause of vesical schistosomiasis. Rarely *S. mansoni* may be involved. The adult worms inhabit the venules of the vesical and pelvic plexuses and the eggs are deposited primarily in the bladder and urinary tract.

**Morbid Anatomy.** The pathological changes depend upon the intensity and duration of the infection. Inflammation of the bladder by the eggs develops with ulceration and papilloma. There is an extensive hyperplasia of the bladder wall which becomes greatly thickened and inelastic. The ureters become indurated and thickened and the urinary flow is obstructed with resultant pathological changes in the kidney. The urethra may become inflamed and occluded and the prostate, seminal vesicles and vagina heavily infiltrated with eggs. The eggs in the bladder, urethra and kidneys become surrounded by concretions of uric acid oxalate phosphates and eventually calcium. Secondary bacterial infection contributes to the ulcerations of these various organs.

**Symptomatology.** Symptoms may not develop for years in light infections but in heavy infections symptoms may be first noticed as early as one month after infection. The eggs first appear in the urine in seventy to eighty-four days. The most characteristic symptom is a painless hematuria usually with blood in the terminal drops of urine although the whole output may be bloodstained. As the mucosal

**Life Cycles.** *Taenia saginata* or beef tapeworm measures 15 to 20 feet or more in length and consists of a thousand or more proglottids. The head is about pinhead in size 1.5 to 2.0 mm in diameter and has four suckers but lacks hooks. The terminal gravid proglottids are about 20 mm long and 3 mm wide and contain approximately 100,000 eggs. When freshly passed they are white very active and crawl about like inch worms. They may creep out of the anus exuding eggs about the perianal region from the ruptured ends of the parasite's uterus. Eggs are also shed in the bowel and are infectious when passed in the stool. Cattle and allied animals the only known intermediate hosts ingest the eggs when grazing on land contaminated with human excreta. The eggs hatch in the cow's small intestine liberating the six hooked embryos which migrate by the blood stream primarily to muscle and in three months develop into bladder worm larvae *Cysticercus bovis*. In the United States and other countries where beef is eaten with only the surface seared leaving the interior raw the cysticerci may be only warmed not killed. When man ingests thus infected meat the head of the tapeworm enclosed in the cyst is freed attaches to the intestine grows into a complete tapeworm in two to three months and may live as long as 25 years.

*Taenia solium* or pork tapeworm measures 6 to 10 feet in length and consists of less than a thousand proglottids. The scolex is smaller than the head of a pin about 1 mm in diameter has four suckers and a circle of hooks. Gravid segments either singly or in short chains are passed by man and eggs are not consistently found in the feces. The eggs are indistinguishable from those of *T. saginata*. Hogs which feed on human feces become infected and within three months the bladder worm *Cysticercus cellulosae* develops giving rise to "measly" pork. Eggs ingested by man also develop into cysts. Man becomes infected with the adult tapeworm by eating inadequately cooked pork. This infection is uncommon in the United States but is prevalent in parts of Asia some countries of Europe and in Latin America. An unsolved problem of parasitology is the frequency with which the cysticerci are found in hogs in countries where human infection with the adult worm is extremely rare.

*Diphyllobothrium latum* the fish tapeworm is the largest tapeworm of man growing to a length of 30 feet or more with 3,000 to 4,000 proglottids. The long narrow head is provided with a longitudinal groove on either side. Unlike *Taenia* the mature proglottids discharge their eggs as they are produced. A single worm produces as many as one million eggs per day. These operculate eggs when discharged into fresh water develop in several weeks and a ciliated six hooked embryo (coracidium) escapes. The free swimming embryos are eaten by water fleas of the genus *Diatomus* or *Cyclops* in which they develop into a procercoid the first larval stage. Fresh water fish eat the infected water fleas and a plerocercoid the second larval stage matures in the muscle of the fish. This larval form when eaten in raw or insufficiently cooked fish attaches to the small intestine of man and develops into a mature worm in five to six weeks. Some of the finest species of game fish constitute the source of human infection. This cestode is common in Europe Russia Japan parts of Africa and Canada. In the United States it is present in the Great Lakes area especially in Scandinavians. There are small endemic foci in Florida and California and in South America in Chile and Argentina. Refrigerated fish shipped from

endemic areas to urban centers in the United States serve as a source of many infections. Jewish women and children who taste their gefilte fish as they season it during its preparation are not infrequently infected.

*Hymenolepis nana* or dwarf tapeworm is the smallest tapeworm of man measuring only several centimeters in length. Heavily infected patients may harbor several thousand of them. Four suckers and a crown of hooks are present on the head. Posterior proglottids disintegrate in the small intestine liberating eggs which are characterized by the presence of a pair of polar filaments. The eggs which are passed in man's stool are infectious and require no intermediate host. When swallowed the enclosed six hooked embryo invades the intestinal villi and develops into a tapeworm cyst (cercocystis). This larval tapeworm breaks out of the villus into the intestinal lumen and becomes a strobilate worm in two weeks. Although *Hymenolepis nana* is able to complete its entire life cycle in a single host it also can utilize fleas and grain beetles as intermediate hosts. This parasite is cosmopolitan and is the commonest cestode of man. As would be expected from its mode of transmission it is more prevalent in children than in adults. *Hymenolepis nana* from rats and mice will infect man but not with the same facility with which it infects its normal hosts.

*Hymenolepis diminuta* or rat tapeworm has been reported several hundred times in man including a number of infections in the United States. The actual number of infections is probably much greater. Its intermediate hosts are larvae and adults of various meal moths grain beetles and fleas. Man becomes infected by eating cereals harboring these infected insects.

*Dipylidium caninum* a common tapeworm of the dog and cat has been reported occasionally as a parasite of man. Fleas and lice of dogs or cats serve as intermediate hosts of this worm therefore it may be found in young children. One of the writer's patients at the age of four months harbored four mature worms indicating that the infection had occurred by the age of two months. Infected fleas or lice may accidentally enter the mouth of an infant or the baby may be infected by having its face licked by a dog that has just nipped a flea.

**Symptoms.** Although a patient usually harbors one or only a few *Taenia saginata* or *T. solium* as many as 143 *D. latum* and several thousand *H. nana* have been recovered. The clinical picture may be due to the number and mass of worms present the trauma produced at the sites of attachment and reaction to the metabolites of the worms. Tapeworm infection frequently produces no symptoms and the patient becomes aware of his infection only when segments are passed in the stool or are found in the underclothing. Tapeworms may be harbored for years and except for the inconvenience of the gravid segments crawling out of the anus the host continues in robust health enjoying both food and drink.

In one study 47 of 100 patients harboring *T. saginata* complained of abdominal pain described as a vague ache or hunger pain relieved by food colicky and stabbing

- Gelfand M and Ross W F The Distribution of Schistosome Ova in the Alimentary Tract in Subjects of Bilharziasis Tr Roy Soc Trop Med & Hyg 47(3) 215 1953

### SCHISTOSOME DERMATITIS (Swimmers Itch)

**Etiology:** Schistosome cercariae of several avian and mammalian hosts penetrate the skin of man but can progress no further and are destroyed in the skin producing a dermatitis. A number of migratory birds including several species of ducks harbor the adult worms and wherever in their travels the suitable fresh water snail host is present the dermatitis may be found in man. Recognition of this clinical entity is gradually expanding the known geographical distribution of the disease. It was first recognized in Michigan in 1928 and now is extensively distributed in the United States, Canada, Europe, Mexico, Central America, Japan, Malaya, Australia, India, Africa, Alaska, South America, Cuba, and New Zealand. Marine forms cause a dermatitis among clam diggers and sea bathers on the east and west coasts of the United States and in Hawaii.

**Symptoms:** The skin penetration of the cercariae is accomplished by lytic secretions and the action of their anterior spines. Within a few minutes a prickling sensation begins and persists for a half hour leaving small macules. Several hours later the macules begin to develop into papules and some may become pustules. Intense itching and edema accompany these lesions which reach their maximum in three days and subside in a week. Scratching may lead to secondary infection. Individuals vary markedly in their susceptibility. The reaction to repeated infection is more severe presumably because of a local sensitization.

**Treatment:** Antipruritic and antihistaminic lotions are of palliative value. Antimicrobial drugs should be used for secondary bacterial infection.

**Prevention:** Removal of snails from bathing beaches and the destruction of aquatic growth which may harbor them is a practical method of preventing the infection. A mixture of two parts copper sulfate and one part copper carbonate at the rate of three pounds per 1000 square feet of bottom is lethal to snails. Cercarial penetration of the skin usually takes place as the

film of water on the skin evaporates. In an experimental infection brisk drying with a towel reduced the number of cercarial lesions on one leg to one lesion in contrast to 125 on the other leg on which the water dried slowly.

## Cestode or Tapeworm Infections

### (Cestodiasis)

Cestodiasis is an infection with species of tapeworms. The mature worm (strobila) consists of a head (scolex) the organ of attachment which is provided with suckers and usually with anterior hooklets, the neck situated immediately behind the head which constitutes the region of growth of the tapeworm and a chain of successive segments (proglottids) which arise from the distal end of the neck and become larger and more mature sexually as their distance from it increases. Each mature proglottid is a complete hermaphroditic reproductive unit. The tapeworms do not have a digestive tract but absorb food through their body wall. The mature egg of human tapeworms contains an oncosphere or hexacanth embryo. After the oncosphere stage there are one or more larval stages before the worm is ready to mature. Most tapeworms require two or three hosts for the completion of their life cycles.

Human tapeworm infections are of two types: (1) those in which the mature worm is attached to the bowel wall—intestinal cestodiasis and (2) those in which man harbors the larval form in various organs of his body—visceral and somatic cestodiasis.

### INTESTINAL CESTODIASIS

**Etiology:** Thirty or more species of tapeworms produce intestinal infection in man. Only six of these are common as human parasites. They are as follows: *Taenia saginata* (beef tapeworm), *T. solium* (pork tapeworm), *Diphyllobothrium latum* (fish tapeworm), *Hymenolepis nana* (dwarf tapeworm), *H. diminuta* (rat tapeworm) and *Dipylidium caninum* (dog tapeworm).

ing 40 to 75 pounds 0.4 gm 76 to 100 pounds 0.6 gm 100 pounds and over 0.8 gm

**Oleoresin of Aspidium** An emulsion consisting of 50 gm or ml of oleoresin of aspidium 80 gm of acacia and water to make up to 60 ml is very effective. One half of the dose is given early in the morning followed by the second portion one hour later. The total dose for children is 40 ml of the emulsion per 10 pounds of body weight.

**Iodothyrone Acid (Prodax)** This preparation which is used for the visualization of the gallbladder was recently reported by Shookhoff and Sterman to be effective against tapeworms. They give 30 gm to children weighing 40 pounds or less and suggest 60 gm for children of 100 pounds. They consider it the drug of choice for use in children as it is well tolerated and unlike quinacrine hydrochloride or oleoresin of aspidium does not cause vomiting.

**Prevention** Prevention consists of (1) eating only thoroughly cooked pork (*T. solium*) beef (*T. saginata*) and fish (*D. latum*) which contain the larval stages (2) the sanitary disposal of human excreta (3) protection of food against contamination by man, mice and rats (*H. nana* and *H. diminuta*) (4) treatment of dogs and cats to free them of fleas and lice and to remove *D. caninum*.

## VISCERAL AND SOMATIC CESTODIASIS

The larval forms of several tapeworms give rise to echinococcosis (*E. granulosus*) cysticercosis (*T. solium*) cenurosis (*Multiiceps*) and sparganosis (*D. mansoni*).

### ECHINOCOCCOSIS

(Hydatid Disease)

**Etiology** Echinococcosis is caused by the larval stage called hydatid cyst of the tapeworm *Echinococcus granulosus*. The adult tapeworm is found in the dog and its relatives and the cysts commonly in

sheep swine cattle camel and man. *Echinococcus multilocularis* which produces an alveolar hydatid cyst in man is contracted through the tapeworm eggs in the feces of foxes.

**Life Cycle** The adult *E. granulosus* is 3 to 9 mm in length and consists of a scolex with four suckers and a crown of hooks, a neck and three segments. It lives attached to the upper portion of the dog's small intestine. The dog becomes infected when it is fed animal organs containing *Echinococcus* cysts. The tapeworm eggs are passed in the dog's feces contaminating the environment. Sheep and other intermediate hosts ingest the eggs while grazing. Children and man probably pick them up from infected soil or by fondling dogs whose fur is contaminated. The ingested eggs hatch in the duodenum and the six-hooked embryo penetrates the intestinal wall and is carried by the lymphatics and blood stream to the organs of the host. The larva undergoes vesiculation and the resultant cyst gradually develops.

**Morbid Anatomy** The distribution of 1802 cysts in man recorded by the Australian Hydatid Registry was: liver including secondary peritoneal seeding 63.3 per cent, lung 24.5 per cent, muscles and fascia 4.6 per cent, bone 2.6 per cent, kidney 2.2 per cent, spleen 1.3 per cent, brain 0.9 per cent, heart 0.3 per cent, thyroid 0.1 per cent, breast 0.1 per cent, and parotid, prostate and pancreas 0.1 per cent. The cysts are usually more or less spherical and consist of (a) an outer non-nucleated hyaline laminated layer (b) an inner germinal layer (c) straw-colored fluid filling the cyst (d) daughter cysts and (e) brood capsules containing scolices (hydatid sand). The germinal layer secretes the laminated membrane and brood capsules arise by proliferation of its nucleated cells. Scolices are formed within the brood capsule from buds of its inner surface. Innumerable brood capsules may be formed and on rupturing their scolices escape into the mother cyst where they are known as hydatid sand. Endogenous daughter cysts probably arise from the germinal membrane, brood capsules or scolices. Exogenous daughter cysts arise from herniations of the wall of the mother cyst.

**Geographical Distribution** *Echinococcus* has a cosmopolitan distribution with areas of heavy infection in sheep raising countries where diseased organs are discarded to the dogs. Especially heavy infection rates among dogs, domestic animals and man are found in South Africa, Australia, New Zealand, the Punjab (India), Mediterranean countries, sheep raising areas of South America and among the Eskimos of Canada and Alaska. In Canada the moose wolf dog cycle provides man with the infection. This parasite is not uncommon in man in the United States but except for 40 autochthonous cases the infection is found in immigrants from Eastern Europe or was acquired in other foreign endemic areas. The size of the cysts makes their detection at meat inspection almost certain and condemned organs are rendered noninfectious when they are cooked for tannage. Echinococcosis is uncommon in dogs in the United States. The prevalence of such soil-borne human helminths as *Ascaris* and *Trichuris* in the southern United States indicates that favorable conditions for the spread of the eggs of *Echinococcus* are present.

**Symptoms** The symptoms of echinococcosis are those of a slowly growing tumor.

Pain was frequently associated with digestive disturbances such as distention vague discomfort a gnawing sensation hungry feeling flatulence and nausea One third of the patients complained of giddiness especially when hungry but only 7 per cent experienced an increase in appetite Weight loss occurred in some patients but most of the group maintained their weight and some even gained weight Constipation and diarrhea were not significant A mild anemia was present in less than 10 per cent of the patients eosinophilia of 6 to 13 per cent in 10 per cent of the patients and a relative lymphocytosis in 30 per cent of the group

*Diphyllobothrium latum* perhaps because of its great size and the presence of multiple worms apparently is responsible for more symptoms than the other tapeworms Anemia due to this infection is present in less than 1 per cent of the patients afflicted Few of the infections originating in the United States have had an accompanying history of tapeworm anemia The anemia is hyperchromic with erythrocyte counts as low as 500 000 per cu ml and a color index of 1.07 A leukopenia and varying degrees of eosinophilia may be present The gastric acidity is usually normal Complete remission of the anemia follows expulsion of the tapeworm There is a rapid regeneration of erythrocytes and a marked reticulocytosis begins within a week if the extrinsic factor is present Van Bonsdorff's studies suggest that because of the parasite's effect on the reaction of intrinsic and extrinsic factors anemia is more common in patients whose tapeworm is attached high up in the intestine It is postulated that the tapeworm absorbs the intrinsic factor *D. latum* actively absorbs 10 to 50 times as much vitamin B<sub>12</sub> as do other tapeworms

Light infections with *H. nana* usually produce no symptoms other than vague abdominal distress due to a mild enteritis Children harboring hundreds of these worms may experience abdominal pain diarrhea headache and minor nervous disturbances Slight anemia and eosinophilia may be present

**Diagnosis** The diagnosis of the large tapeworms is commonly made by the patient's recognizing characteristic proglottids in his feces or underclothes Segments of *T. saginata* and *T. solium* have lateral genital pores and these two species can be differentiated by the number of lateral uterine branches The proglottids of *D.*

*latum* are broader than long the dark egg filled uterus is rosette shaped and the uterine pore is in the middle of the segment Proglottids or artifacts which are digested beyond recognition should be teased apart and searched under the microscope for eggs which remain intact although the segment has disintegrated The eggs of all of the tapeworms will also be found in the stool those of *H. nana*, *H. diminuta* and *D. latum* with greatest regularity The large tapeworms are sometimes detected by roentgenography following a barium meal

**Treatment** Quinacrine hydrochloride (Atabrine) is the drug of choice against tapeworms Oleoresin of aspidium is equally effective but is potentially more toxic Both of these drugs lose some of their effectiveness in children because of the frequent occurrence of vomiting following their administration Either adults or children who vomit these drugs may be successfully treated by duodenal tube Recently iodoalphonic acid (Priodax) has been demonstrated to be of value against tapeworm in children Preparation of the patient is necessary before an anthelmintic is administered On the day preceding treatment the patient should be placed on a liquid diet and supper should be omitted except for black coffee tea or water A soapsuds enema should be given in the evening A saline purgative should be given to patients under treatment for *Hymenolepis nana* the evening preceding treatment The patient should remain in bed and the following morning breakfast is omitted and the anthelmintic administered Two hours after the administration of the last dose of anthelmintic a saline purge is given to flush out the injured or dead worm If the worm is not brought out by purgation or if the head is not recovered a soapsuds enema should be given since the worm or scolex may be lodged in the large intestine Toilet paper used by the patient should not be placed in the bedpan as it makes the search for the tapeworm head very difficult The large tapeworms are frequently removed by a single course of therapy *H. nana* infections are much more difficult to cure because of the large number of worms usually present

**Quinacrine Hydrochloride (Atabrine)** The adult dose of quinacrine hydrochloride is 0.8 gm To prevent vomiting the total dose may be divided in two portions and given at a half hour interval Children are given the following total dose those weigh

available Chemotherapy is entirely ineffective It is possible that roentgen irradiation may be of value Biotherapy consisting of the injection of increasing amounts of hydatid fluid in an attempt to desensitize the tissues and kill the parasite has been tried in patients with multiple or inoperable cysts

The location size and condition of the cyst determine the surgical course to be pursued As more than one cyst is present in 25 to 50 per cent of the patients exploration is necessary Alveolar osseous and multiple cysts are often not amenable to surgery Extensive spread of the cysts in the pleural and peritoneal cavities may require multiple operations over a period of years to allay pressure If the cyst is unilocular and there is danger of its rupture during removal the cystic fluid may be replaced by 1 per cent formalin and allowed to act for five minutes or sufficient commercial formalin should be injected to give the cystic fluid a 2 per cent concentration to kill the germinative portions Whenever possible the cyst should be enucleated but a calcified cyst of the liver might be kept under observation without surgery Marsupialization may be necessary especially when the cyst is infected The skin test remains positive for years after removal of the cyst but the complement fixation test soon becomes negative

**Prevention** In endemic areas avoidance of contact with dogs or their contaminated environment is important in the prevention of hydatid cyst Children especially should be protected and taught the value of hand washing Periodic deworming of dogs with arecoline hydrobromide is necessary to keep them free of *Echinococcus* Carcasses of sheep hogs and cattle should be inspected at slaughter and organs infected with cysts destroyed Dead animals should be buried to prevent dogs from feeding upon them

#### CYSTICERCOSIS

**Etiology** Cysticercosis is infection with the cyst stage of *Taenia* The cyst usually involved is *Cysticercus cellulosae* of the pork tapeworm *T. solium* Cysticercosis of man due to *T. saginata* the beef tapeworm has been reported only occasionally

**Life Cycle** Man may acquire the cyst by the ingestion of *T. solium* eggs from contaminated soil or food As the egg is infectious when passed in the stool patients harboring the adult worm may become infected through anus to mouth contamination Auto infection may occur through regurgitation of the eggs or segments into the stomach by reverse peristalsis The eggs hatch in the upper in-

testine and the embryos migrate by way of the lymphatics and blood stream to various organs of the body They develop into translucent bladder worms 5 by 10 mm in two to three months

**Symptoms** The invaded organs in order of frequency are the subcutaneous tissues muscles brain eye heart lung and peritoneum The presence of hundreds of cysticerci in the subcutaneous tissues and muscles may go unnoticed or may cause only slight muscular discomfort As many as 20 000 cysticerci have been found in one patient In the brain the cysticerci vary in number size and location If single or few in number they may cause no symptoms As long as the cysticerci remain alive minimal inflammatory reaction develops The dead parasite causes local inflammatory tissue reaction and capsule formation Epileptic seizures and other disturbances due to tumor may be present Ventricular cysticerci may produce blockage of cerebrospinal fluid There may be an increase in cerebrospinal fluid glucose total cell count and eosinophils In countries where *T. solium* is prevalent as high as 10 per cent of the brain tumors are cysticerci Surgical removal is the only treatment available but this may not be practical if the cysticerci are numerous Invasion of the eye by *Cysticercus cellulosae* may lead to uveitis iritis detachment of the retina and hemorrhage The parasite is unencapsulated and constantly changes shape

**Diagnosis** The diagnosis of cysticercosis except in endemic centers is difficult and usually awaits excision of the larva The presence of an adult *T. solium* in as many as 25 per cent of the patients with cerebral or ocular cysticercosis is of considerable diagnostic significance Likewise the presence of subcutaneous cysticercosis is often accompanied by a similar infection of the brain The onset of epileptic seizures after childhood in endemic areas suggests cysticercosis Biopsy of subcutaneous cysticerci gives a specific diagnosis Calcified cysticerci are visible on roentgenographic examination Eosinophilia is inconstant as are intradermal and complement fixation reactions

#### CENUROSIS

A cenurus is the larval stage of tapeworms belonging to the genus *Multiceps* the adults of which live in the intestines of dogs and cats Sheep and rabbits are the usual hosts of the cenurus It has been reported in man 10 times *Coenurus cerebralis* infection which localizes in the brain is usually

and depend upon the organ involved A cyst may attain considerable size and may extensively involve an organ without causing symptoms The rate of growth is extremely variable and depends upon restriction of the invaded tissue Nutrition also is apparently important for in vascular organs like the spleen and lungs the growth of the cyst is rapid The average growth is 1 to 2 cm in diameter per year

As all of the hexacanth embryos entering the portal stream pass to the liver this organ is the most common site of hydatid cysts The right lobe of the liver harbors the majority of the cysts which are often single The liver is extraordinarily tolerant to the presence of this parasite and calcified cysts 8 to 10 cm in diameter often produce no symptoms despite years of residence in this organ Liver function is usually not significantly altered but transient jaundice due to pressure on the biliary tract may be present Ascites and enlargement of the abdominothoracic veins may follow cystic pressure in the area of the portal fissure Large cysts may produce a sense of weight accompanied by nausea and distention after meals Rupture of hepatic cysts may cause extension into the liver or into the lungs and frequently results in an extensive invasion of the lowest portion of the peritoneal cavity The multitude of liberated brood capsules daughter cysts and scolices grow apace Pressure on the colon urinary bladder and ureters is often the patient's first present ing symptom

*Pulmonary echinococcosis* occurs twice as frequently in the right lung as in the left The cysts are surrounded by adventitial capsules of considerable thickness Cough is a common symptom Pain is rarely severe and usually takes the form of discomfort or a feeling of a weight in the chest Hemoptysis is frequently present and may be induced by coughing Rupture of pulmonary cysts may cause pneumonia anaphylactic shock extensive pleural invasion or simply evacuation of the cyst contents through the bronchus

*Hydatid cysts of the brain* fortunately are rare They are more common in children than in adults and because of the slow growth of the parasite may have a considerable period of latency The usual signs and symptoms of an expanding tumor are present Jacksonian epileptiform seizures followed by paralysis are often present Cardiac cysts may be silent may perforate into the pericardium or may produce dissemination throughout the

blood stream kidney cysts may cause pain hematuria and altered kidney function

Secondary bacterial infection of cysts occurs especially of those in the liver The latter may be diagnosed as cholecystitis The suppurative process may extend into the peritoneal cavity and give rise to a subphrenic abscess or general peritonitis

Puncture or rupture of hydatid cysts may produce toxic manifestations in sensitized persons These anaphylactic reactions may consist of only urticarial wheals with general or localized erythema and pruritus Other symptoms of variable occurrence are fever cyanosis dyspnea abdominal pain vomiting diarrhea and syncope As the anaphylactic state is abolished by general anesthesia grave symptoms rarely if ever occur during operation even if much hydatid fluid is spilled into the operative area

**Diagnosis** The clinical diagnosis of hydatid cyst is based upon the presence of a cystic tumor often in a patient enjoying good health Hydatid thrill is extremely rare and the cysts are often too tense to show fluctuation Roentgenographic examinations are especially valuable in diagnosis and unsuspected cysts are often located The cysts are identified by their spherical shape fluid content calcified wall and adventitial thickening Laboratory diagnosis of pulmonary cysts may be made by finding scolices brood capsules or cyst fragments in the sputum or in the urine in kidney cysts Exploratory puncture for diagnostic purposes is dangerous as it may result in an anaphylactic reaction or dissemination of the infection Eosinophilia is very irregular in hydatid disease and is unreliable for diagnosis The intracutaneous test (Casoni) using hydatid fluid gives 75 to 95 per cent positive reactions Consequently a negative reaction is of relative value in excluding the presence of infection Reactions are most frequently positive when the cyst is in the liver and lungs but are often negative with cysts of the brain and bones A positive complement fixation test is also of value and suggests that the infection is still active A hemagglutination test is being developed

**Prognosis** In general the prognosis of echinococcus cyst is good but depends upon the site of the cyst and the possibility of its rupture and spread Alveolar cysts because of their extensive spread and invasiveness are most dangerous Repair of bones invaded by cysts is usually unsatisfactory

**Treatment** Surgical removal of the hydatid cyst is the only successful therapy

variety of carnivorous and herbivorous animals. The chief reservoir for human infection is swine. The incidence of infestation in hogs fed on grain or allowed to root in the field is about 15 per cent, but in those fed on uncooked garbage it is in the range of 5 per cent. The meat becomes infectious within seventeen days after the pig ingests the parasite.

The epidemics which occur are small and are usually confined to a family or group which has held a picnic or barbecue. Infection may follow the tasting of raw pork as in the preparation of sausage. In meat products prepared commercially from the pooled muscles of many hogs the infected sample is so diluted that the infestation in any given person is light though it may be spread among many people. Only about 70 per cent of the pork raised in this country is processed in plants which are under close supervision, hence a large part of the country's total supply of pork products may carry live parasites. As much as 10 per cent of the sausage in large city markets has been found infected. It has been estimated that each American consumes three servings of trichinous pork in a year. The cysts do not calcify in pork and are almost invisible to the naked eye, hence they are not looked for in the government inspection of meat. No economically feasible technique for detecting trichinella infection in hogs by anatomical or immunological methods has been developed.

Autopsy studies indicate that approximately 16 per cent of the human population is infected; this incidence is the same in both sexes. The fact that the number and density of infections are greater in older patients suggests many separate invasions of the body by a small number of parasites. The greater prevalence of the disease in the Midwest and other areas where Germans and Italians have settled reflects local customs in the preparation of food.

**Pathogenesis and Morbid Anatomy.** Invasion of the intestine by the adult parasite produces little local reaction. About the seventh day the larvae enter the general circulation and are widely distributed to all tissues; they then break out of capillaries between muscle fibers and penetrate into serous cavities and even into the cerebrospinal fluid. In initial infections invasion of striated muscle fibers produces necrosis, hyaline degeneration and an inflammatory response consisting of polymorphonuclear neutrophils, lymphocytes and variable num-

bers of eosinophils. The reaction of the body produces around the coiled trichina a cyst which begins to calcify between six and eighteen months after invasion and in which the larvae may live for ten years or more.

The heaviest infestation occurs near the tendinous portion of the diaphragm of the gluteus pectoralis, deltoid, gastrocnemius or intercostal muscles, in that order of frequency. The extraocular muscles, the masseters and the muscles of the larynx may also be involved. The heart is invaded but the parasite seems unable to establish itself in cardiac or smooth muscle.

In approximately four fifths of the human infections proved at autopsy less than ten trichinae per gm. of muscle are present—a degree of infection which probably produces few symptoms. In some cases however as many as 1000 trichinae per gm. of muscle may be found.

In reinfections the muscle walls of arterioles may show degenerative and inflammatory changes similar to those seen in serum sickness and periarteritis nodosa—a finding which suggests an allergic or immune reaction. The fatty change found in the liver in fatal cases probably results from inadequate intake of protective foods. The renal tubules occasionally show degenerative changes which are reflected clinically by albuminuria. The bone marrow shows hyperplasia, chiefly in eosinophilic myelocytes.

**Pathological Physiology and Chemistry.** The mechanism responsible for the development of edema is obscure. The number of capillaries mechanically ruptured is inadequate to explain it, and production of a toxin by the parasite or by the destruction of muscle has never been demonstrated. Measurements of the fluid space in animals indicate that the increased permeability of capillary walls and of cells may result from an immune reaction.

In some instances the blood chlorides and total serum proteins (particularly the albumin fraction) are decreased and the nonprotein nitrogen is elevated.

In cases with neurological involvement the cerebrospinal fluid may contain erythrocytes and increased amounts of protein.

**Symptoms.** The symptoms are highly variable and depend largely upon the degree of infection. If the meat is heavily infected the invasion of the intestinal mucosa one to four days after ingestion may cause local irritation producing symptoms of nausea, vomiting and diarrhea which resemble those of food poisoning. In other

fatal It has been reported once from the United States in a 26 month-old child from Nevada At autopsy a cenurus 3 cm in diameter was found in the frontal section of the brain and numerous budding vesicles covered the ventral aspect of the pons and medulla oblongata

#### SPARGANOSIS

Sparganosis is due to infection with the second larval stage of the tapeworm *Diphyll lobothrium manson* of the dog This larva called a sparganum or plerocercoid may be acquired by ingesting water containing water fleas (Cyclops) harboring the first larval stage (proceroid) by eating raw infected (plerocercoid) flesh of snakes frogs birds and mammals or by applying their parasitized tissues to an inflamed or ulcerated site Infections of the eye are produced by the latter method The sparganum may grow as long as 30 cm and

may cause considerable inflammatory reaction especially in the abdominal wall and orbital region Surgical removal of the sparganum is the only treatment available The disease is found primarily in the Far East but is also present in Africa Europe Australia North and South America

## The Nematelminthes (Roundworms)

Nematoda or roundworms infecting man vary greatly in size are unsegmented and are cylindrical in shape They are completely covered by a cuticular acellular layer There is a complete digestive tract and the sex organs are greatly elaborated occupying the major part of the body cavity Most nematodes are oviparous but a few are larviparous Eggs of some species are fully embryonated and infectious when laid others require a period of incubation within or outside the human body Eggs of some nematodes hatch in the soil grow and metamorphose into infective stage larvae Several nematodes require an intermediate host for completion of their larval development Man acquires most nematode infections by the ingestion of infectious eggs but hookworm and strongyloides larvae actively invade the skin filaria larvae gain entrance into the skin after escape from their blood sucking insect hosts and Trichinella infections are acquired from infected pork

The following important nematode infections of man will be considered here trichinosis trichuriasis strongyloidiasis ascariasis visceral larva migrans enterobiasis filariasis dracunculosis hookworm and creeping eruption

HAROLD W BROWN

### Trichinosis

(Trichiniasis Trichineliasis)

**Definition** Trichinosis is an infestation of striated muscle by the larvae of the roundworm *Trichinella spiralis* It is transmitted by inadequately cooked food and is one of the greatest uncontrolled public health problems in this country

**Etiology** Live encysted larvae of the parasite are ingested in meat After being liberated by protein digestion they anchor themselves to the mucosa of the duodenum and jejunum from which they extract oxygen and liquid food Within the next two days they develop into sexually mature adults—the males 1 mm and the females 3 to 4 mm in length After copulation the male may die but the female burrows deeper into the mucosa The eggs develop and hatch in utero About 1500 larvae (which are 100  $\mu$  in length) are discharged through the vulva in the anterior fifth of the body into the lymphatics and lacteals of the host's small intestine at the rate of one each half hour over a period of approximately six weeks the female then dies

**Epidemiology** The parasite exhibits no specificity for species and can infect a wide

count is usually between 10 000 and 20 000 per cu mm. The eosinophilia precedes the development of positive skin or serological reactions but may be absent in severe infections or suppressed by a simultaneous bacterial infection. In subclinical or very mild cases the eosinophil count is of no diagnostic value. Eosinophilia may persist for five to seven years.

Reversible changes in the T waves may be detected by electrocardiograms after the second week of the disease.

**Prognosis.** In subclinical or mild infections the prognosis is excellent in small epidemics the mortality may vary from 5 to 30 per cent. The overall mortality must be low since few patients in whom the infestation is detected at autopsy have had clinical symptoms suggestive of the disease. In individual cases the ultimate prognosis is poor if symptoms particularly pronounced diarrhea develop within two days of exposure or if little evidence of immune response can be detected by eosinophil counts, skin tests or serological reactions. Most patients who die succumb to pneumonia or cachexia between the fourth and sixth weeks.

**Treatment.** No specific treatment is known. If the parasite can be demonstrated in the suspected meat while the patient is still having gastrointestinal symptoms administration of an anthelmintic such as piperazine citrate (which is also effective in related parasitic infestations) in doses of 10 to 15 gm twice daily for seven days may remove some of the adult worms.

No drug has been found effective against the larvae. After encystment of the parasite has begun the damage is done.

In human cases and in experimental animals the administration of corticotropin (ACTH) or adrenal corticosteroids has reduced the acute manifestations of the disease. The benefit probably results from suppression of host response to the presence of the parasite or its products. The dose and duration of hormone therapy must be carefully adjusted to the individual case.

Because of the tendency to hypoproteinemia a high protein diet is probably of some value in supportive therapy. In very heavy infections with severe symptoms and marked edema caution should be exercised in the administration of crystalloids such as glucose and saline. Infusions may be necessary to overcome dehydration but unless the intravascular osmotic pressure is maintained with plasma or human serum albumin circulatory collapse may be produced by fluid replacement therapy.

The muscular aching may require the intermittent administration of analgesics such as salicylates. It is possible that the administration of antihistamine drugs from the second to the fifth week might reduce the allergic manifestations of the disease.

**Prevention.** All the basic scientific facts necessary for complete prevention of trichinosis in human beings have been known for years. Trichinae can be killed by cooking or irradiation. Smoking pickling and other methods of processing or preserving meat do not kill the parasite. Pork should be cooked at a minimum temperature of 140° F for at least thirty minutes per pound otherwise large roasts may not be completely done in the center. Freezing of meat at 0° F (—18° C) for at least 24 hours or at 5° F (—15° C) for twenty days will usually kill all trichinae. These preventive measures are effective and their general use has been shown by autopsy studies to reduce the incidence of human infection.

### Trichuriasis

(Whipworm Infection, *Trichocephalasis*)

**Etiology.** The adult *Trichuris trichiura* measures 30 to 50 mm in length; the female is usually longer than the male. These parasites have a characteristic whip-like shape: the handle of the whip comprising the posterior two fifths and the delicate narrow esophagus the anterior three fifths. They live primarily in the cecum and colon of man.

**Life Cycle.** The female worm passes several thousand barrel-shaped eggs daily which bile stain to a beautiful golden brown. Embryonation of the egg takes place in three to four weeks in warm moist soil. Man becomes infected by ingesting the fully embryonated egg, the shell of which is weakened in the upper intestine where the larva is freed. The young worm temporarily attaches to the small intestine later passing to the site of its adult attachment in the cecum where it grows into an adult.

cases these symptoms may be entirely absent

Beginning on the seventh day the migration of the larvae usually produces muscular weakness stiffness or pain accompanied by remittent fever which may reach  $104^{\circ}\text{F}$  ( $40^{\circ}\text{C}$ )—a rare finding in disease caused by larger parasites. The fever may persist for several weeks and usually drops by lysis. The elevation of temperature as well as occasional transient skin rashes probably results from the liberation of foreign protein since a large number of larvae are destroyed during their migration. Depending upon the muscles invaded the patient may note backache which resembles that of influenza or pain on chewing swallowing breathing or moving the eyes or limbs.

Next to the muscular symptoms edema is the most common finding; it may appear at any time after invasion. Edema is most frequently manifested as puffiness around the eyes involving the upper lids though it may be generalized. Many of the protean manifestations of the disease result from the involvement of arterioles and from the edema. Symptoms in the central nervous system such as headache delirium and psychic or visual disturbances suggest encephalitis but are usually transient. Hemiplegia or localized paralysis occasionally occurs and may be permanent. Dyspnea may result from the edema and from invasion of the muscles of respiration. The great variety of symptoms the variation in their intensity and the lack of regularity in the course are characteristic of trichinosis.

After encystment the only symptom may be vague aching in the muscles.

**Diagnosis.** A clinical diagnosis is extremely difficult to make except in cases of heavy infection. The early gastroenteritis is nonspecific. The most useful physical signs are tenderness to pressure on the muscles edema especially about the eyes the splinter hemorrhages under the nails or in the conjunctivae. Only a fraction of the cases are recognized and reported.

Laboratory methods are helpful for confirmation of the diagnosis but are of little aid in therapy. If a portion of the suspected meat can be obtained it should be ground in a household meat chopper and digested in hydrochloric acid and pepsin. After the suspension has been digested for an hour several portions are examined for larvae by means of a dissecting microscope.

Examination of the stools for adult worms is useless. During the stage of mi-

gration larvae can occasionally be found in the centrifuged blood.

Beginning ten days after infection the larvae may be found in biopsy specimens removed from the tendinous insertion of the deltoid or gastrocnemius muscle. One gram of the unfixed muscle should be spread between two pieces of plate glass measuring roughly 18 by 12 by 0.6 cm compressed with screw clamps and examined under the low power microscope. During the second or third week the larvae may be parallel to muscle fibers and are sometimes difficult to recognize. After encystment they can hardly be confused with anything else. The samples removed at biopsy are usually too small to examine by the digestion technique. Routine methods of cutting and staining microscopic preparations rarely detect the parasite and show only myositis.

The simplest diagnostic procedure is the intradermal skin test performed by injecting 0.1 ml of a 1:10,000 dilution of dried powdered trichinae dissolved in saline. A positive reaction is usually not obtained before the end of the third week of the infection. The skin reaction may be immediate (wheal) or delayed (tuberculin) in type. Many false positive tests are obtained; some are group cross reactions due to infestations with closely related parasites (such as *Trichuris* the whipworm) but the significance of most is unknown. The skin test usually remains positive for about seven years.

Immunological tests made on the patient's serum after the third week of the disease and utilizing the precipitin complement fixation or flocculation techniques are more specific but may not be positive in an overwhelming infection. Involvement of the reticuloendothelial system particularly with Hodgkin's disease may give rise to false positive reactions. The most accurate serological reaction uses living trichinella larvae suspended in the patient's serum; a highly refractive precipitate forms around the worm. This mechanism probably explains how most of the ingested living larvae are prevented from penetrating the intestinal mucosa in reinfections. The serological tests revert to negative after a year.

In acute infections caused by a moderate number of parasites the eosinophils in the peripheral blood will begin to increase ten days after infection reaching a peak in the third or fourth week. The proportion of eosinophils may vary from 5 to 70 per cent and the total leukocyte

## Strongyloidiasis

(*Strongyloidosis*)

**Etiology** Strongyloidiasis is a chronic intestinal infection caused by a delicate nematode *Strongyloides stercoralis*. The disease is due to the presence of adult worms in the gastrointestinal mucosa and to the migration of larvae through the intestinal mucosa and other organs.

**Life Cycle** The parasitic female is 2.2 mm in length and lives partially buried in the mucosa of the duodenum and jejunum but in heavy infections may be found from the pylorus of the stomach to the rectum. A parasitic male worm has been described which is practically indistinguishable from the free living male. The writer collected several thousand parasitic females at an autopsy but was unable to find a single parasitic male. Single larval infections of the rat strongyloides always produce fertile parasitic female worms indicating that parthenogenesis occurs. The parasitic female worm lays thin shelled eggs which embryonate within the glands of the stroma and epithelium of the mucosa. The escaping rhabditiform larvae burrow out to the intestinal lumen and initiate three types of life cycle: (1) In the direct cycle the rhabditiform larvae pass out in the feces and develop in the soil into infectious filariform larvae which penetrate man's skin. (2) In the indirect cycle the rhabditiform larvae pass out in the feces and in the soil develop into free living male and female worms. The female lays eggs that hatch into rhabditiform larvae which develop into infectious filariform larvae. (3) In the hyperinfective cycle the rhabditiform larvae develop into the filariform stage in the intestine and by penetrating the intestinal mucosa or perianal skin establish a cycle within the host without leaving the body (autoinfection). Internal hyperinfection explains strongyloidiasis in persons who have been out of endemic areas for as long as thirty six years. Filariform larvae in the soil penetrate human skin on contact and enter the venous blood stream. They are carried to the right heart and lungs. They penetrate the pulmonary capillaries into the alveoli and migrate up the respiratory tree to the pharynx and are swallowed. The worms grow considerably during this migration and the young forms when they arrive in the duodenum burrow into its wall and within twenty eight days from skin exposure begin to lay eggs.

**Geographical Distribution** Strongyloidiasis is cosmopolitan and parallels the distribution of hookworm but usually is somewhat less prevalent. It occurs in the rural southern United States and has been found as far north as New York State. Dogs and cats may harbor *Strongyloides* but they are not favorable hosts. Man is the important reservoir.

**Pathology** The invasion of the skin by the filariform larvae may cause erythematous papular eruptions. Napier described a periodic petechial urticarial or linear eruption with bathing trunk distribution. The adult females, eggs and larvae are found in the intestinal mucosa and by toxic and lytic action produce an eosinophilic inflam-

matory reaction in the lamina propria. Larvae may migrate through the muscularis and serosa into the peritoneal cavity. Migration of larvae through the lungs especially in large numbers as encountered in the hyperinfective cycle produce localized inflammatory reaction and hemorrhage. The cellular response consists of polymorphonuclear neutrophils, eosinophils, mononuclears and endothelial cells. The bronchial epithelium is involved and congestion of the bronchioles may trap the migrating larvae which metamorphose into adults. Larvae are found throughout the lung in the pulmonary arterioles, alveoli, subpleural and intrapulmonary lymphatics. Larvae have been found in large numbers in the liver and in practically every organ of the body usually surrounded by eosinophilic granulomata.

**Symptoms** Although larval penetration of the skin causes some inflammation and itching, the history of "ground itch" often cannot be elicited (see Hookworm Disease, p. 407). As *Strongyloides* and hookworm are frequently present in the same patient it is impossible to identify the cause of the ground itch if it is present. Light infections frequently cause no intestinal symptoms. In moderate infections abdominal pain is the most common symptom and it is often associated with periodic watery diarrhea alternating with constipation or normal bowel movement. Severe infections usually due to autoinfection cause anemia, appetite loss, nausea, vomiting, emaciation and dysentery. Fever, cough and a tender liver indicate massive larval migration. During the early and acute phases of the infection a leukocytosis of 8000 to 20,000 per cu mm with a 10 to 50 per cent eosinophilia is characteristic. In chronic infections the leukocyte count may be within normal limits with 2 per cent to 10 per cent eosinophils. Overwhelming infections with fatal termination have been associated with (1) paralytic ileus, (2) hepatitis, cholecystitis and myocarditis, (3) *E. coli* bacteremia and meningitis, probably spread by the massive larval migration from the intestine to the blood stream. Genitourinary complications with a history of nocturia, incontinence, urgency, genital urticaria and larvae in the urine have been reported.

**Diagnosis** Clinical diagnosis is uncertain as hookworm, *Trichuris* and *E. histolytica* infections may produce somewhat similar clinical pictures. The presence of rhabditiform larvae in a fresh stool is diag-

worm in several months. The adult worm lives for many years.

**Epidemiology.** *Trichuris trichiura* is a cosmopolitan parasite of the warm moist regions of the world. It is frequently one of a trinity of infections (hookworm, *Ascaris* and *Trichuris*). Stoll calculated the world prevalence of *Trichuris* infection to be 355 million. In the United States *Trichuris* has a spotty distribution and occurs abundantly only in areas where there is dooryard pollution, dense shade close to the house and a heavy rainfall. These conditions are especially prevalent in the southern Appalachians and southwestern Louisiana. As many areas in Puerto Rico meet these environmental conditions, heavy infections are frequently encountered in emigrants from that Commonwealth. In general, children are more frequently and more heavily infected than adults.

**Pathology and Symptomatology.** *Trichuris* lives primarily in the cecum of man but is also found in the appendix and lower ileum. In heavily parasitized persons the worms are distributed throughout the colon and rectum and they may be seen on the prolapsed rectal mucosa that results from straining at the frequent stools. The worm embeds its long threadlike anterior end into the intestinal mucosa.

Light infections usually do not give rise to recognizable clinical manifestations and the presence of the parasite is discovered only on routine stool examination. In a group of 81 patients with uncomplicated heavy *Trichuris* infection, Swartzwelder noted that abdominal or epigastric pain was the most frequent complaint and that it was often accompanied by localized areas of tenderness. Nausea and vomiting, constipation, distention and flatulence, slight fever and headache also occurred relatively frequently. Approximately one half of the patients had a tentative diagnosis of some form of appendicitis; the chronic form predominating. Patients with very heavy chronic *Trichuris* infections present a characteristic clinical picture consisting of severe anemia, frequent small blood-streaked diarrheic stools, abdominal pain and tenderness, weight loss and occasional rectal prolapse with worms embedded in the mucosa. Extreme cachexia is sometimes seen and fatal termination in children, harboring from 400 to 4100 worms, has been reported. *Trichuris* may attach to the appendiceal mucosa and may provide an entrance for pyogenic bacteria and subse-

quent acute or subacute inflammatory processes.

The anemia that accompanies *Trichuris* infections may be marked with a hemoglobin value as low as 3.0 gm. The worms apparently suck the blood of their host and hemorrhage may occur at the site of their attachment. Not infrequently the *Trichuris* infection is accompanied by other helminth and protozoan infections, making it impossible to determine the exact role of *Trichuris* in the anemia. An eosinophilia is encountered in uncomplicated *Trichuris* infections, especially recently acquired infections. Chronic infections may be accompanied by a moderately elevated or normal eosinophile count.

**Diagnosis.** As light infections are usually asymptomatic and heavy infections may be confused with hookworm disease, amebiasis or appendicitis, stool examinations are necessary for a definitive diagnosis. The simple smear technique will detect most of the infections but it may be necessary to employ a concentration technique in light infections. An egg count using Stoll's method will give an approximation of the intensity of infection and is useful in assessing the results of treatment.

**Treatment.** The treatment of *Trichuris* infections by means of anthelmintics administered orally until recently has been only moderately satisfactory. Tetrachloroethylene, hexylresorcinol and oil of chenopodium remove some of these parasites but repeated treatment frequently fails to eliminate the infection completely. This failure is probably due to the worm's position in the ileocecal region which prevents the orally administered anthelmintic from reaching the parasite in lethal concentration.

Recently, Dithiazanine 3-ethyl-2-[5-(3-ethyl-2-benzothiazolynylidene)-1-pentadienyl]benzothiazolium iodide given orally has been shown to be very effective, complete cures being achieved with 200 mg three times a day for three to five days.

**Prevention.** As trichuriasis is associated with soil pollution and personal cleanliness, prophylaxis depends upon sanitary disposal of feces and education in hygiene.

infiltration asthmatic attacks and edema of the lips. Some instances of Loeffler's syndrome and tropical eosinophilia have been attributed to migrating *Ascaris* larvae. Instances of endophthalmitis have been observed for which the eye was removed and the sections revealed nematode larvae which were probably *Ascaris*. Koino ingested 2000 embryonated *Ascaris* eggs of human source at one time and thereby demonstrated that large numbers of larvae simultaneously migrating through the lungs may cause a serious hemorrhagic pneumonia. Keller, Hillstrom and Gass noted

widening in the hilar regions and increased bronchovascular marking in the chest roentgenograms of a group of Tennessee children infected with *Ascaris*. Fiske in Nigeria attributes the high bronchopneumonia rate in children of over five months of age to the migration of *Ascaris* larvae. Encephalitis and meningitis have been reported in *Ascaris* infected patients suggesting that the migrating larvae may reach the brain more commonly than is realized.

Serious and sometimes fatal effects of ascariasis are due to the migrations of the adult worms. They may be regurgitated and vomited escape through the external nares or rarely be inhaled into a bronchus. Many instances of invasion of the bile ducts, gallbladder, liver and appendix have been reported. The worms may carry intestinal bacteria to these sites and stimulate the production of abscesses. The worms may penetrate the intestinal wall migrate into the peritoneal cavity and produce peritonitis. Continuing their migration they may come out through the body wall usually at the umbilicus in children and the inguinal region in adults. Intestinal volvulus, intussusception and obstruction may also result from *Ascaris* infection. Carbon tetrachloride as used for hookworm treatment and fever are two of the causative factors of *Ascaris* migration.

Even when the worms cause little or no traumatic damage the byproducts of living or dead worms may produce marked toxic manifestations in sensitized persons such as edema of the face and giant urticaria accompanied by insomnia, loss of appetite and weight, extreme nervousness and in extreme cases cachexia. Some workers believe that they can demonstrate physical and mental retardation in infected children but factors such as heredity, malnutrition and other parasites confuse the clinical picture. Young pigs infected with *Ascaris* do not gain weight normally and it is possible that the human *Ascaris* may

affect children similarly. This action may be due to the food actually consumed by the worms or to the trypsin inhibiting substance which they produce interfering with the host's protein digestion.

**Diagnosis.** The large number of eggs passed by the female worms assures the diagnosis by the microscopic examination of simple smears of the patient's stool. Fertilized eggs are very characteristic with their bile stained mammillated outer shell but unfertilized eggs assume bizarre shapes and may be mistaken for debris by the untutored or unsuspecting. Rarely one encounters infections consisting of only immature worms; only male worms or worn out female worms and hence eggs are not present in the stool. These infections are sometimes incidentally discovered by roentgenographic examination after a barium meal. Either the worm displaces the barium or the barium is retained in the worms' ribbon-like intestinal tract after the host has evacuated the barium. A first-class department of radiology will detect such infections from time to time when the laboratory has reported the stool negative for eggs. The spontaneous passage of one or more worms by anus or mouth does not necessarily mean that additional worms are present. This can be verified by stool examination two or three days after the worms have been evacuated.

**Treatment.** Piperazine salts are safe and very effective in ascariasis; a single dose will cure 75 to 85 per cent of the infections. A dose on two consecutive days will eliminate approximately 95 per cent of the infections. Piperazine can be given at any time of day since the presence of food in the digestive tract has little if any effect on its activity against *Ascaris*. Purgation is not required. The ascariides are usually passed relaxed though still alive by the patient on the first, second or third day after treatment. Piperazine citrate syrup has been used successfully in partial intestinal obstruction due to ascariasis combined with abdominal decompression with a Levin tube and supportive therapy.

Dosage Schedule for One and Two Day Treatment of Ascariasis with Piperazine Citrate

PATIENT'S WEIGHT (lbs.)	DAILY DOSE OF CITRATE SYRUP (ml.)	DAILY DOSE AS HEXAHYDRATE (gm.)
30-50	20	2.0
51-100	30	3.0
101 and over	35	3.5

nostic If hookworm is also present its eggs will be found in the early stages of segmentation In stools that are several days old the larvae that are found may be either hookworm or Strongyloides The advantage of a fresh stool specimen for diagnostic examination is obvious Duodenal aspirates are sometimes positive when stool examination fails to reveal larvae Sedimentation of the stool will often detect light infections missed by simple smear examination Strongyloides eggs are rarely found except in purged stools

Prognosis is favorable except in exceedingly heavy infections involving hyperinfection which may be accompanied by other debilitating diseases

Treatment Gentian violet tablets with a 1½ hour enteric coating are moderately effective The adult dose of 0.065 gm is given orally with meals three times daily for seventeen days As parasitic females deep in the intestinal mucosa are difficult to reach and migrating larvae and adults elsewhere in the body are not affected by oral medication it is often necessary to repeat the therapy Abdominal pain nausea vomiting diarrhea and constipation not infrequently accompany gentian violet therapy but unless severe intolerance is encountered the patient should be encouraged to continue treatment

A cyanine dye Vanquin given orally at the rate of 0.050 gm three times a day at meal times for seven days has recently been tried with considerable success Nausea is encountered during therapy with Vanquin and vomiting and diarrhea may occur Dithiazanine given by mouth in a dosage of 200 mg three times a day for twenty one days is reported to have cured 92 per cent of a group of adult patients

Prevention consists of sanitary disposal of human excreta wearing shoes and treatment of detected infections

## Ascariasis

**Etiology** Ascariasis is caused by *Ascaris lumbricoides* man's largest intestinal roundworm which has been one of his closest companions since the Stone Age

In ancient times when man was distinguished from other animals only by his upright position rather than by food or sanitary habits the vast majority of men probably harbored this parasite Over the centuries as man's habits and sanitation gradually changed from those of a quadruped to those of modern man this ubiquitous parasite has partially lost its hold on him although Stoll recently estimated that 644 400 000 of the earth's population harbor *Ascaris* Some 3 000 000 in the United States especially inhabitants of the mountainous and hilly areas of the South are hosts of this persistent parasite Surveys have demonstrated 60 to 70 per cent of the children and 15 to 20 per cent of the adults in some of these rural areas to be infected A combination of soil pollution near dwellings and moderate moist climate is essential for the propagation of this parasite The practice of using night soil on growing vegetables probably contributes to the *Ascaris* problem in many areas especially in the Orient

**Life Cycle** Adult ascarides are 15 to 35 cm in length and as usual among nematodes the male is smaller and less consequential than the female They live in the small intestine of man subsisting on the intestinal content The female worm passes some 200 000 eggs per day which is an indication of the slight likelihood of an infective egg successfully reaching another human host The eggs are passed in the feces and go through an embryonic development in the soil which takes three to four weeks before the infective larval stage is complete Once the larvae are fully matured within the shell the eggs remain viable in the soil for months but do not hatch When ingested by man the eggs hatch in the upper small intestine and the emergent larvae penetrate the intestinal wall and migrate via the mesenteric lymphatics and veins to the liver vena cava right heart and pulmonary arteries to the lungs They break out of the pulmonary capillaries into the air sacs migrate up the respiratory tree crawl over the epiglottis are swallowed and in sixty to seventy five days become adult worms in the lumen of the small intestine The life span of the adult worm is approximately one year

**Symptomatology and Pathology** The usual infection consisting of a dozen or so worms often goes unnoticed by the host and is discovered only on a routine stool examination or by the discovery of an adult worm passed spontaneously in the stool The most frequent complaint of patients infected with *Ascaris* is intestinal colic or vague abdominal pains An eosinophilia is present during the larval migration but patients harboring the adult worms may exhibit little or no eosinophilia During the lung migration the larvae may produce host sensitization which results in allergic manifestations such as pulmonary

larvae have been found in the liver brain spinal cord lungs cardiac muscle kidney and lymph nodes During the migratory phase the larvae may be found in normal tissue some distance ahead of the progressive linear lesion later becoming enclosed in a granuloma Similar lesions of the retinal fold and vitreous membrane of the eye due to hookworm larvae have been reported

**Symptoms** To date the syndrome visceral larva migrans has been recognized only in children from one to four years of age A history of close contact with the soil dogs or cats and dirt-eating may be elicited The disease frequently follows a benign asymptomatic course characterized by a marked persistent eosinophilia of 20 to 80 per cent and hepatomegaly Intermittent fever cough anorexia failure to gain weight muscle pain joint pain abdominal pain dermatitis and neurological disturbances may be present in more severe infections Pneumonitis is occasionally present and pulmonary infiltration may be seen in roentgenograms of the chest The spleen is seldom enlarged Skin rashes on the lower extremities have been reported

A number of the children have exhibited marked anemia and eosinophilia accompanied by a high total leukocyte count There is usually a marked increase in blood globulins largely gamma globulin The liver function tests are often normal although the cephalin flocculation test may be positive The erythrocyte sedimentation rate may be elevated Albumin was present in the urine of several children The larvae of several nematodes may cause choroiditis iritis and hemorrhage A recent study of the eyes of 24 children (aged 3 to 13 years) removed because of a clinical diagnosis of retinoblastoma revealed nematode larvae

**Diagnosis** The diagnosis of *Toxocara* infections is usually established on clinical grounds with the triad of marked eosinophilia hepatomegaly and hyperglobulinemia The last named finding is of cardinal importance in diagnosis In severe infections liver biopsy and the demonstration of typical eosinophilic granulomatous lesions and larvae confirm the diagnosis Skin tests and serological reactions employing antigens prepared from various nematodes have given promising although equivocal results

The differential diagnosis may include trichinosis hepatitis eosinophilic leukemia Loeffler's syndrome familial eosinophilia miliary tuberculosis asthma whooping

cough retinoblastoma endophthalmitis and liver invasion by adult *Capillaria hepatica* (nematode)

**Treatment** As only a few infections with visceral larva migrans have been recognized therapy is still in the experimental stage Arsenicals and the piperazine Heptazan have been used in an attempt to kill the larvae but with disappointing results Corticotropin or adrenal corticosteroids may be of value in ameliorating hypersensitivity reactions Epinephrine may also be of value Broad spectrum antimicrobial drugs are suggested for pulmonary involvement Treatment at present is largely supportive and symptomatic including antianemic measures

**Prevention** Small children should be protected against contact with infected dogs and cats especially kittens and puppies which are more commonly and heavily infected Animals under six months old should be dewormed every month and older ones every two months Worms passed as a result of treatment should be destroyed Dog and cat stools passed in children's play areas should be buried and sandboxes which offer an attractive defecating area to cats should be covered when not in use There is no satisfactory chemical for killing the ova in soil

## Enterobiasis

(Oxyuriasis Pinworm or Seatworm Infection)

**Etiology** Enterobiasis familiar to most physicians as oxyuriasis is due to a small white worm *Enterobius vermicularis* The female worm is 8 to 13 mm in length and because of its pointed tail is named the pinworm Unlike many helminths Enterobius is not limited to the rural and the poor but is found in all urban economic

Dithiazanine is effective against *Ascaris*. The adult dose is 200 mg three times a day for five days.

Hexylresorcinol is an effective ascaricide and has been used extensively. The one precaution that must be taken with hexylresorcinol is to be certain that the intestinal tract is empty when the drug is given as it will combine with food and have little action on the parasite. The dose of hexylresorcinol is 0.1 gm for each year of age up to 10 years. Hexylresorcinol (Crystoids Anthelmintic) is available in pill form and should be swallowed with a little water. When children are treated it is essential to see that the pills are actually swallowed and that none remain in the mouth to be chewed later since a superficial burn will be produced. The patient should refrain from eating for five hours after treatment. A magnesium sulfate purge is given on the following morning to hasten the expulsion of the injured and dead worms. The ascarides are not all passed immediately after treatment but may appear in the stool over a period as long as ten days. Therefore the post-treatment stool examination should be delayed for two weeks from the date of treatment. If eggs are still present a second treatment may be given. Approximately 90 per cent of all the ascarides are removed with a single treatment and 60 to 80 per cent of the patients are completely freed of their infection.

Santonin is not very effective in safe doses. Oil of chenopodium, an effective ascaricide, has caused a number of fatalities, apparently among persons who are especially sensitive to it.

**Prevention.** Prevention consists of the disposal of human excreta in sanitary privies or toilets. Children must be taught to use these facilities and to avoid contamination of hands and food with soil. Fresh vegetables grown in areas where human excreta is used for fertilizer should be thoroughly washed and preferably cooked. Swine harbor an ascarid morphologically similar to the species in man but it is evidently physiologically distinct and is not a source of human infection.

## Visceral Larva Migrans

**Etiology.** The name visceral larva migrans has been given to a clinical syndrome resulting from the invasion of human viscera by nematode larvae normally parasitic in lower animals. Dog and cat ascarides of the genus *Toxocara* are apparently the most common cause of the disease. Aberrant human *Ascaris Strongyloides* and hookworm larvae may occasionally produce the syndrome.

**Life Cycle.** The dog and cat ascarides *Toxocara canis* and *T. cati* are widely distributed throughout the world. Undetected human infections with their larvae are probably more widespread than the reports from the United States. England and Puerto Rico would indicate. The adult female worms are 10 to 12 cm in length and produce numerous eggs which are passed in the feces of the host. In moist soil the eggs become embryonated in several weeks. When ingested by dogs or cats the larvae hatch in the small intestine and migrate through the intestinal mucosa and by way of the blood stream to the liver, lungs, bronchial tree and trachea; they are swallowed again and mature in the small intestines of these animals. In man the larvae hatch from ingested embryonated *Toxocara* eggs, penetrate the intestinal mucosa and are carried by the blood stream to the liver, lungs and other organs and there they remain as larvae, seldom completing the cycle to adulthood in the intestine. These larvae apparently migrate through the various organs stimulating typical eosinophilic granulomata. Experimental evidence indicates that the larvae can remain alive a year or more in man. The varied clinical manifestations may be due to the number of larvae, their location and the individual patient's response to their presence. One patient with a severe infection was found to harbor 60 larvae per gm of liver, 11 per gm of muscle and 3 to 11 per gm of brain tissue. Repeated infections with larval nematodes in abnormal hosts frequently result in the development of allergic reactions. Hence the infection may become clinically significant in hypersensitive individuals.

**Pathology.** The characteristic lesion has most frequently been encountered in the liver and consists of gray elevated circumscribed areas approximately 4 mm in diameter. Microscopically these granulomatous lesions consist of eosinophils, lymphocytes, epithelioid cells and giant cells of foreign body type surrounding the larva. Extensive hepatic parenchymal necrosis may be present and Charcot-Leyden crystals may be seen. Eosinophilic granulomatous lesions are numerous and are encountered in practically every organ of the body. Lesions containing *Toxocara*

of three consecutive days will detect the majority of infections although as many as six swabs on different days may be necessary to ensure a positive diagnosis. Mothers often discover the female worms on the outside of a freshly passed stool or crawling in the anal region of the child soon after he has been put to bed.

Although the eosinophil count may be slightly increased in the presence of *Enterobius* it is of no diagnostic significance since many infected persons have normal counts.

**Treatment** The treatment of a person harboring pinworm is frequently unsatisfactory if other infected members of the household are untreated and remain as a source of infection. It is recommended therefore that all members of the household be examined by the Scotch tape swab technique and that all those found infected be treated simultaneously.

The piperazine salts citrate phosphate and diplicate are the drugs of choice against enterobiasis and are available as a palatable suspension in tablets or wafers for chewing. Piperazine is most effective against pinworm when taken before breakfast followed by a glass of water which carries the drug to the cecum and colon the source of the worms. Therapy is continued for ten consecutive days employing the following dosage:

Table 1. Dose of Piperazine Used in Therapy of Enterobiasis

Age	PIPERAZINE CITRATE SYLPH (ml)	EQUIVALENT PIPERAZINE HEXAHYDRATE (gm)
Up to 2 years	2.5	0.25
2 to 6 years	5.0	0.50
6 to 12 years	10.0	1.0
Over 12 years	20.0	2.0

The writer cured 58 of 60 patients with the seven-day course of piperazine. Overdosage with piperazine may result in nausea, vomiting, dizziness, difficulty in focusing vision and urticaria.

Gentian violet in enteric-coated tablets is an effective inexpensive therapeutic agent for the treatment of enterobiasis. A course of ten consecutive days of therapy is effective and relatively well tolerated. Even a seven-day program of therapy has been reported as successful. The usual adult dose of gentian violet is 0.065 gm (1 grain) three times a day before meals. Children are given 10 mg per year of age; thus a ten-year-old would receive a total

of 100 mg a day or 33 mg (0.5 grain) three times a day.

Several cyanine dyes are effective on oral administration in enterobiasis. Van quin is given for five to eight days in a dosage of 0.6 to 0.7 mg per kg of body weight three times a day. Dithiazanine also gives a high rate of cure after only five days of therapy at the adult dose of 100 mg three times a day. Nausea and vomiting may accompany therapy with these two compounds and gentian violet.

It has been shown that zinc oxide ointment liberally applied to the perianal region four times daily for 21 days results in a cure of 80 per cent of pinworm infection. This regimen probably prevents reinfection and retroinfection and although it is not as effective as piperazine therapy it might be combined with piperazine therapy in refractory infections.

**Prevention** Since poor personal hygiene plays an important part in acquiring and perpetuating the infection, education concerning handwashing after toilet and before meals is indicated. Thorough daily bathing of the perianal region should help reduce infection. During treatment and for a week thereafter a diaper or close fitting cotton pants will prevent contamination of the hands and dissemination of the eggs. The diaper or pants should be boiled daily and the bed sheets and night clothes boiled two or three times a week. Dogs and cats do not harbor pinworms and hence play no part in its spread. The administration of piperazine on one or two days a week is effective in controlling the infections in institutions for children.

#### Filariasis

**Etiology** Filariasis is an infection with one or more species of threadlike nematodes. The adult worms live in various parts of the human body and the female gives birth to delicate elongated (150 to

classes even in the seats of the mighty. No other helminth parasite of man enjoys such an extensive geographic distribution. In general children are more commonly infected than adults. Negroes appear to be less susceptible to pinworm than white persons.

**Life Cycle.** The adult worms inhabit the cecum and adjacent portions of the colon and ileum where they presumably feed on the intestinal contents although it has been suggested that they may attach themselves to the intestinal wall and consume cellular material. The mature female worm usually does not pass her eggs into the intestinal lumen but stores them within her body until she contains some 11 000 at which time she migrates down the colon and out the anus. On reaching the perianal region the worm is stimulated presumably by the lower temperature and altered environment to expel her eggs in great numbers. These eggs become infectious within a few hours. Ingested eggs containing infective larvae are acted upon by the digestive juices of the upper gastrointestinal tract and the larvae are freed in the duodenum. They migrate down the intestine to their site of predilection where they complete their development in as short a period as fifteen to twenty-eight days although some worms may take twice this length of time.

There are several methods of transmitting pinworm infection. Perhaps the most common among children is the direct anus-to-mouth transference of eggs by contaminated fingers and the contamination of food by soiled hands. This source of infection may be especially important in individual reinfection as eggs are frequently found beneath the fingernails of infected children.

Pinworm eggs become dislodged from the perianal region of the host and may be widely disseminated in the environment. These eggs may be carried to the mouth on hands or food or may become airborne and thereby swallowed or inhaled. Thus Nolan and Reardon report that 91.7 per cent of 241 dust samples collected in households with pinworm infected members contained *Enterobius* eggs. Eggs were recovered in dust from floors, baseboards, tables, chairs, davenport seats, dressers, shelves, picture frames, window sills, toilet seats, wash basins, bath tubs, bed sheets and mattresses. The largest number of eggs was found in bedrooms. This study demonstrates how the infection may spread through families or groups living in the same environment. It is surprising that any member of a family should escape infection when there are several infected persons in close association with him and in view of the large number of eggs produced by the female pinworm. Pinworm eggs have been isolated from the dust of schoolrooms and a school dining room which presumably could serve as the original source of infection for children. Schuffner and Swellen grebel present data suggesting that larvae may escape from eggs in the perianal region of the host and reentering the colon by way of the anus produce what they term a "retro-infection".

The simple life cycle of *Enterobius* closely associated with man in all stages explains the ease with which it reinfects its host, spreads through families and children's institutions and has assured its survival despite the elaborate sanitary facilities developed by modern man.

Fortunately for man the eggs of *Enterobius* are relatively susceptible to climatic conditions and in a warm, dry environment they survive only a few hours or days. This probably explains why over

90 per cent of the eggs recovered by Nolan and Reardon in household dust were not viable.

**Symptoms.** It is not uncommon for both adults and children to harbor pinworms without noticeable symptoms. Pruritus ani caused by the migrating female worms is perhaps the commonest complaint of infected persons. Various observers have ascribed a number of signs and symptoms to the presence of pinworm such as poor appetite, weight loss, hyperactivity, enuresis, insomnia, irritability, grinding of the teeth, abdominal pain, nausea and vomiting but it is often difficult to prove the causal relationship of pinworm. The various symptoms have been attributed to mechanical stimulation and irritation by the adult parasite, by allergic reactions and by the transportation of intestinal bacteria by the pinworm to sites where they are pathogenic.

The relation of pinworm to appendicitis is problematical. Ashburn found *Enterobius* in 7.9 per cent of 2317 surgically removed appendices. The worms were found as frequently in normal appendices as in those showing chronic inflammation and more frequently in normal than in acutely inflamed appendices. Ashburn concluded that no cases of appendicitis oxyurica were present in his series. Other workers including Schwarz and Straub have demonstrated penetration by the worm of the appendiceal wall accompanied by a foreign body reaction and abscess formation. They conclude that pinworm may be a primary cause of appendicitis. Occasionally the female worms migrate into the vagina and produce an intense vulvitis. They may continue their migration into the fallopian tubes and uterus and become encapsulated.

**Diagnosis.** The usual methods of stool examination used for other intestinal parasites are of little value as *Enterobius* eggs are usually not present in the stools. The best routine method of diagnosis is by means of the Scotch tape swab. A piece of Scotch tape 2 inches long is folded sticky side out over the end of a tongue depressor and pressed firmly against the perianal region. The tape is then placed sticky side down on a microscope slide and examined under the low power of the microscope for the typical eggs which are characterized by a relatively thick shell flattened on one side containing a partially developed larva. The swabs should be taken soon after the patient arises in the morning before bathing as the worms frequently migrate to the perianal region during the night. A swab made on each

the Pacific area during World War II. These recurrent attacks are characterized by funiculitis epididymitis orchitis retrograde lymphangitis of the extremities and localized areas of swelling and redness of the arms and legs. Fever, chills, headache, vomiting and malaise may accompany these attacks which last from several days to several weeks. Somewhat similar acute attacks may occur at monthly or longer intervals in patients with or without elephantiasis. Usually the affected extremity becomes red, hot and very painful. Therapy with antimicrobial drugs is usually unsuccessful, indicating a verminous rather than bacterial etiology.

**Obstructive Filariasis:** Elephantiasis is the dramatic end result of filariasis. Many mistakenly believe that it is the inevitable termination of every filarial infection but fortunately the grossly enlarged scrotum or leg is the exception rather than the rule. Elephantiasis has been reported in 1 to 70 per cent of infected natives in various parts of the world. Obstructive filariasis develops slowly, usually follows years of continuous infection and is preceded by chronic edema and often by repeated acute inflammatory attacks. Adenitis, varix, hydrocele, chylocele and elephantiasis of the legs, scrotum, arms, breasts or vulva are end results. Of 2595 United States marines with clinically diagnosed filariasis, only 22 per cent showed objective signs other than shotty lymph nodes and only 0.2 per cent developed severe sequelae. Abscesses of the pelvis of the kidney, epididymis, retroperitoneal tissues, inguinal nodes and iliopectineal muscles may result from the dead and degenerating worms. These abscesses may be sterile but frequently pyogenic bacteria are present.

**Diagnosis:** The clinical diagnosis of filariasis will depend upon a history of exposure to mosquitoes in an endemic area in conjunction with the clinical findings discussed above. The blood should be examined for microfilariae by placing a drop obtained at night on a slide and examining it under the low power of the microscope for actively moving microfilariae. To determine the species of microfilariae, thin or thick blood smears stained with Wright or Giemsa stain will bring out the diagnostic characteristics. To detect light infections, 1 ml of night blood is taken in 9 ml of a 2 per cent formalin solution. The sediment is examined directly or may be allowed to dry on a slide and then stained. The blood of patients with clinical filariasis does not always contain micro-

filariae. Approximately a year elapses from the time of infection until the worm matures and produces microfilariae; hence during the early months of clinical inflammatory filariasis, microfilariae will not be found in the blood. Likewise late in the disease, by the time elephantiasis is present, the adult worms and microfilariae may both have died. The intradermal test using *Dirofilaria immitis* antigen and the complement fixation test are of diagnostic value when microfilariae cannot be found in the blood. Biopsy of enlarged lymph nodes or lymphatics may disclose living or dead adult worms or the characteristic histological picture of filariasis.

**Treatment:** It is common knowledge in endemic filaria areas that rest and moving to a cool climate reduce the number and severity of the acute inflammatory attacks. Diethylcarbamazine (Hetrazan) which is given orally is quickly lethal to microfilariae and either kills the adult females or permanently sterilizes them. The dosage is 2 mg per kg of body weight three times daily for seven to fourteen days. Headache, dizziness and malaise may be encountered during therapy. Numerous antimony and arsenic compounds have been tried against infections with the adult worms. Arsenamide is probably the most effective yet it is somewhat toxic and 15 intravenous doses are required. Antimicrobial drugs are useful in recurrent lymphangitis due to secondary streptococcal infection. Streptococcal vaccines have also been advocated for this condition.

The massive edema that precedes and accompanies elephantiasis of the legs may be alleviated by pressure bandaging. Administration of adrenal corticosteroids to patients with elephantiasis may be followed by a diuresis and an increased number of microfilariae in the blood stream. Both effects are ascribed to a lessening of the inflammatory reaction around the adult worms which allows freer lymphatic drainage from the smaller limb. Various operative measures have been tried in elephantiasis. The removal of the enlarged scrotum is usually successful and results in permanent cure. The repair of enlarged legs attempting to provide anastomosis between the deep and superficial lymphatics is not entirely satisfactory.

**Prognosis:** In light infections, prognosis is good. The prognosis once elephantiasis has developed is not good unless surgery is successful.

**Prevention:** The prevention of filariasis consists of controlling mosquito breeding.

350  $\mu$ ) embryos known as microfilariae. These microfilariae migrate periodically or constantly through the peripheral blood stream or skin (*Onchocerca*) from which they are taken up by the appropriate species of blood sucking fly. Within the insect vector the microfilariae grow and metamorphose into motile infective larvae. These migrate into the proboscis sheath of the fly and at the time of the fly's next blood meal are introduced into or near the puncture wound. The infective larvae then penetrate into the skin and migrate by way of the lymphatics and blood vessels to the various sites where the adult worms mature. Approximately a year elapses from the time of infection until the adult female worm matures and produces microfilariae. This is called the prepatent period.

### BANCROFTIAN FILARIASIS

**Etiology** Bancroftian filariasis is produced by *Wuchereria bancrofti* which lives especially in the lymph vessels and lymphoid tissues associated with the drainage of the legs, genitalia, arms and breasts. Blockage of the lymphatic drainage of these areas by the parasite leads to elephantiasis. This parasite is widely distributed in tropical and subtropical areas.

**Life Cycle** Infection is initiated when the filarial larva is deposited onto or into the skin by infected mosquitoes, especially *Culex fatigans*, although *Anopheles*, *Aedes* and *Mansonia* may also transmit this parasite. Little is known of the subsequent history of these larvae until they mature and the fertilized females begin discharging microfilariae. The adult worms live approximately five years. The microfilariae pass from the vicinity of the parent worms into the lymph vessels and thence into the visceral blood stream. The microfilariae exhibit a nocturnal periodicity and are found in greatest numbers in the peripheral circulation from ten o'clock in the evening to two o'clock in the morning. During the daytime the microfilariae are concentrated in the viscera, especially the lungs. A nonperiodic variety of *W. bancrofti* is found on a number of Polynesian islands. Microfilariae ingested by mosquitoes undergo development and reach the infective stage in ten days.

**Morbid Anatomy** Filarial symptoms are caused by the adult worms. Living worms as well as dead and degenerating ones give rise to inflammatory granulomatous lesions of the lymphatic system. This lymphadenitis and lymphangitis is due largely to allergic reactions in sensitized tissues. The acute inflammatory stage is characterized by edema, eosinophilia, obliterative endolymphangitis and vascular stasis in the vicinity of the worm. A sub-acute stage follows with enlargement of

lymph nodes and dilated sinuses surrounded by macrophages, reticular cells, eosinophils and foreign body giant cells. The endothelium and reticular cells of the lymphatics proliferate, thrombosis may occur and ultimately fibrous obliteration. In the chronic stage the cellular reaction and edema are replaced by fibroblastic hyperplasia, absorption and replacement of the parasite by proliferative granulation tissue and extensive lymph varices are produced. The high protein content of the lymph stimulates the growth of dermal and collagenous connective tissue and gradually over a period of years the enlarged affected parts harden, producing chronic elephantiasis. The site of the obstructive inflammation determines the part of the body which enlarges. Obstruction of the lymphatics with resultant rupture of the lymphatics of the urinary bladder or kidney produces chyluria; those of the tunica vaginalis, chylocele; and those of the peritoneum, chylous ascites.

**Symptoms** Because bancroftian filariasis may run its course over many years it varies greatly in its clinical manifestations. The human reaction to filarial infection is varied and manifold and it is impossible to delimit specifically the disease stages. It is possible however to classify broadly the results of filarial infection into the asymptomatic, inflammatory and obstructive types.

**Asymptomatic Filariasis** In endemic areas children are exposed to infection at an early age and by the age of six years they exhibit microfilariae in their blood without experiencing symptoms referable to their infection. In time the adult worms die and the microfilariae disappear without the patient's being aware of the infection. On physical examination the patient may exhibit a moderate generalized enlargement of lymph nodes, especially of the inguinal lymph nodes. Blood examination discloses numerous microfilariae and a low grade eosinophilia. A survey of the blood of a group from the Virgin Islands considered physically fit for military service revealed that 20 per cent of those examined were infected with filariae.

**Inflammatory Filariasis** The inflammatory filarial infection is an allergic phenomenon due to sensitivity to the products of the living and dead adult worms. Superimposed streptococcal and fungal infections may occasionally be involved. Inflammatory reactions to filarial infections occurred in service personnel one to twenty two months after exposure to infection in

further symptoms. Several courses of therapy may be required.

**Prevention** Prevention consists of the avoidance of water courses along which *Chrysops* hover and the use of repellents.

### ACANTHOCEILONEMA PERSTANS

*Acanthocheilonema perstans* is common in Africa and is also found in South America and Dutch New Guinea. The adult worms are found in the peritoneal, pleural and pericardial cavities. The microfilariae are found in the blood and are nonperiodic. Small biting flies of the genus *Culicoides* serve as the vector of this nematode. The adult worms cause little tissue reaction and most infections are asymptomatic. Massive infection of the liver by microfilariae is reported to cause pain and enlargement of this organ. Edema, Calabar swellings, fever, malaise, headache and drowsiness are attributed to the presence of this parasite. Diethylcarbamazine (Hetrazan) given orally has no effect upon the microfilariae but may have a slight sterilizing effect on the adult female worms. Preliminary studies in which diethylcarbamazine was given intraperitoneally are encouraging.

### MANSONELLA OZZARDI

*Mansonella ozzardi* is found in the West Indies, Yucatan, Panama, the neighboring coast of South America and northern Argentina. The intermediate hosts are small biting flies of the genus *Culicoides*. The adult worms live in the peritoneal cavity in the mesentery and attached fat. There is no evidence that the worm is pathogenic. The microfilariae are found in the blood and are nonperiodic. There is no specific therapy.

### ONCHOCERCIASIS

**Etiology** Onchocerciasis is caused by *Onchocerca volvulus*, the so-called blinding filaria. In Africa it has a wide distribution

but in America it is limited to a narrow strip of coffee growing uplands on the Pacific slope of Guatemala and Mexico and to a more recently discovered focus in eastern Venezuela. It was probably imported to America from Africa in slaves. It has recently been reported in South Arabia.

**Life Cycle** The adult worms are threadlike, the male growing to 4.5 cm and the female to 70 cm. They live coiled in fibrous subcutaneous nodules which vary from the size of a small pea to that of an egg. The adult female passes microfilariae which are found in the nodules and in considerable numbers in the skin of the host but not in the blood. The microfilariae are ingested by the blackfly of the genus *Simulium* when it bites the skin of an infected person. The nodules are found in all parts of the body. In Africa the nodules are most common on the trunk, thighs and arms and in the Americas on the head and shoulders. Although the site of bite of the fly and deposition of the larva may partially determine the site of the nodule, constriction of clothing and skin which temporarily impede the migrating worms leads to their encapsulation in these sites. Some of the adult worms do not become encapsulated, thereby preventing their detection.

**Symptoms** The tumors produced in response to the presence of the adult worms are confined to the superficial connective tissue and do not invade the muscles or viscera. They may be painful, may itch and may become secondarily infected with pyogenic bacteria or may become cold abscesses. Dermatitis is frequently associated with onchocerciasis. An allergic pigmented dermatitis called "mal morado" in Mexico and "erisipela de la costa" in Guatemala, which most often affects the face, is not uncommon. An itching macular rash may develop on the body but especially on the legs. In chronic infections the skin becomes thickened, dark, inelastic and coarse in texture. The legs may become edematous and the inguinal lymph nodes enlarged. The Arabs call the disease "soda," meaning black. It may also be one cause of "craw" or "gale filarienne," a dermatitis accompanied by pruritus. Microfilariae can be found in skin scrapings from these lesions.

**Ocular involvement** occurs in 10 to 85 per cent of those infected and is the most serious complication of this infection. In some areas 5 per cent of those infected have marked visual impairment and become blind. Photophobia, irritation, discomfort and conjunctivitis are the first symptoms. Punctate keratitis, iridocyclitis, vascularization of the cornea and panus gradually develop. The iris thickens, becomes adherent to the anterior surface of the lens and undergoes atrophy.

areas with DDT sprays Spraying the interior of houses is also a valuable control measure Screening of houses and the use of bed nets and repellents are also indicated

### FILARIASIS MALAYI

Filariasis malayi is caused by *Wuchereria malayi* which closely resembles *W. bancrofti*. This parasite is found in the Orient from Indonesia to India Ceylon to China. The adult worms live in the lymphatic system of man. The microfilariae show nocturnal periodicity although they are also present during the daytime in some numbers. The mosquito vectors belong to the genera *Mansonia* and *Anopheles*. The symptoms and pathological changes due to this parasite are very similar to those of Bancroft's filariasis and both acute and chronic manifestations occur. Elephantiasis is common in this infection and it is preponderantly of the lower extremities less common in the arms and rare in the genitalia. Diagnosis is made by finding the characteristic microfilariae in the peripheral blood. Diethylcarbamazine (Hetrazan) is used in therapy but for some unknown reason reactions to the drug are much more frequent than among Bancroftian filariasis patients. Control of this infection is a matter of mosquito eradication. The larval forms of *Mansonia* mosquitoes depend upon water plants (Pistia) for air and the removal of these plants or killing them with herbicidal sprays provides a considerable degree of control.

### LOAIASIS

(African Eye Worm)

**Etiology** Loiasis is caused by *Loa loa* a threadlike worm 3 to 5 cm in length. This disease is confined to west and central Africa especially along the Congo River and its branches. The adult worms wander

extensively throughout the human body and they have been found in many organs at autopsy. However it is their migration in the subcutaneous tissues especially about the face and conjunctiva of the eye that is noticed by the patient. The so-called Mango fly of the genus *Chrysops* which is a diurnal biter is the vector of *Loa*.

**Symptoms** Loiasis is a chronic slowly developing disease in which symptoms do not usually occur until three years after infection and the parasite may persist as long as seventeen years. The parasite may cause considerable irritation but no serious damage. Transient swellings arise which may last for a few days or a week or longer. The swellings (Calabar) arise suddenly are painful may itch may occur subcutaneously on any part of the body and may approach the size of a hen's egg. The wrists and arms are the most common sites. Usually a dermatitis and an eosinophilia of some magnitude are present. These temporary inflammatory reactions are considered an allergic reaction to the products of the worm. Chandler produced a large swelling by the injection of a minute amount of *Dirofilaria* antigen into the skin of a *Loa* infected patient. Similar reactions in the region of the throat urethra bladder and possibly other regions of the body may give rise to pain of unexplained origin. There apparently is no permanent damage due to the Calabar swelling. The migration of the adult worm under the skin of the face and beneath the conjunctiva may cause considerable pain irritation congestion swelling and lacrimation. Quick relief is obtained when the parasite migrates to the deeper tissues.

**Diagnosis** The diagnosis of loiasis is often made by the patient who notes the presence of (1) Calabar swellings (2) the outline and movement of the worm beneath the skin (3) the migration of the worm to the eye. The microfilariae are most numerous in the peripheral blood about midday. Eosinophilia is usually marked. The skin test employing *Dirofilaria* antigen usually gives an immediate positive reaction.

**Treatment** Surgical removal of the worm from the conjunctiva under local anesthesia is effective in the treatment of loiasis. For the intense pain that the parasite causes in the region of the eye Novocaine should be dropped into the conjunctival sac. Hetrazan 2 mg per kg of body weight three times daily for ten days kills the adult worms and microfilariae and prevents

Calcified worms remain for years as hard subcutaneous cords or may be detected deep in the body on roentgenographic examination

**Diagnosis** The diagnosis of dracunculosis is usually made by the patient's noting the presence of cutaneous ulcers and worms in the subcutaneous tissues. Wetting the ulcer may bring forth typical larvae.

**Treatment** Natives extract the worm by winding it on a stick a few centimeters each day. Extraction takes ten to fourteen days. Surgical removal using a local anesthetic and aseptic precautions is usually successful. Elliott reported excellent results from the injection of a phenothiazine emulsion along the path of the worm which causes relaxation of the parasite making it possible to remove it by gentle traction. Rousset's studies indicating that large doses of diethylcarbamazine (Hetrazan) are of therapeutic and prophylactic value should stimulate further investigation.

**Prevention** In the prevention of dracunculosis wells and tanks approached by steps on which persons are able to stand in water as they obtain a supply should be altered and provided with pumps. Biological control of the disease by the introduction of the fish *Barbus pucelli* which feeds voraciously on Cyclops and the guinea worm larvae has proved feasible. For personal prophylaxis boiling or filtering drinking water through coarse cloth is effective.

## Hookworm Disease

(*Ancylostomiasis* *Uncinariasis* *Tropical Chlorosis* *Miners Anemia*)

**Etiology** Hookworm disease is a clinical syndrome caused by infection with *Ancylostoma duodenale* or *Necator americanus*. Hookworm infection implies the harboring of hookworms in the intestine with or without symptoms.

**Life Cycle** The human hookworms measure about 1 cm. in length, the female being slightly larger

than the male. *Ancylostoma* is slightly larger than *Necator*. The adult worms live attached to the small intestine, mainly the jejunum. A female *Necator* produces 5000 to 10,000 eggs per day and *Ancylostoma* twice as many. The larva develops rapidly in the egg and hatches under favorable conditions of moisture and temperature in about 48 hours. The rhabditiform larva hatches from the egg shell and after two moltings within a few days becomes an infective filariform larva enclosed in a transparent sheath. This larva may travel upward or downward in the soil for a few inches as changes in moisture require. Its life span may be several weeks in moist soil, although it does not feed as long as it retains its sheath. When the skin of man is exposed to infected soil, the larva penetrates rapidly, enters a blood vessel and is carried to the lungs where it breaks out into an alveolus. It then makes its way up the bronchi and trachea into the pharynx. It is swallowed and passes into the small intestine where it develops into an adult. About six weeks are required from the time of penetration of the skin until eggs appear in the stools. The life span of the hookworm is several years; the heavier the infection, the shorter the average life span of individual worms. One light experimental infection persisted for 14 years.

**Epidemiology** Hookworm infection is endemic in many parts of the world between 36° north latitude and 30° south latitude. Moisture, warmth, sandy or loose soil, promiscuous defecation, and absence of shoes are the chief factors responsible for infections. A mean monthly temperature of 50° F. is necessary for the development of the larvae in the soil. Regions having less than 40 inches of rainfall a year may show a high incidence of light infections, but rarely have heavy infections. The disease is almost entirely rural except for mines where disposal of excreta is unsanitary.

The hookworm belt in the United States is principally along the Atlantic and Gulf seaboard from North Carolina to eastern Texas. The other important area is the southern Appalachian region including southwestern Virginia, western North Carolina, eastern Kentucky, and eastern Tennessee. Immigrants from rural Puerto Rico frequently harbor hookworm. Recent surveys indicate that there has been a marked reduction in the prevalence of hookworm infection and an even greater reduction in hookworm disease in the South.

Examination of returned American military personnel after overseas service, especially in the Far East, revealed many light infections with *Ancylostoma*.

**Morbid Anatomy** The blood in heavily infected persons presents a picture of microcytic hypochromic anemia. In extreme cases a picture of macrocytic hyperchromic anemia may be present. There is often an eosinophilia ranging up to 25 per cent. The bone marrow shows an increase of erythropoietic cells. The liver may show fatty infiltration. In fatal cases the small intestine usually shows some atrophy of the epithelium and increase in the connective tissue elements of the mucosa. Petechial hemorrhages are found at the site of attachment of the worms. The heart is dilated and its muscle is flabby. There is often edema of the subcutaneous

The eyeball atrophies and with the entrance of microfilariae into the sheath of the optic nerve blindness is complete. Numerous microfilariae are found throughout the structure of the eye and it is probably their secretory products and the toxins from the dead microfilariae which cause the lesions.

**Diagnosis** The presence of subcutaneous nodules, visual disturbance and ocular lesions in persons from endemic areas is suggestive of onchocerciasis. Marked eosinophilia is a constant finding. Very small nodules may be overlooked during physical examination and worms may be present without nodule formation. Demonstration of microfilariae in the skin gives the specific diagnosis. With a sharp razor blade a thin section of skin is removed from near the nodule, skin lesion or from the shoulder area. It is teased out with needles in a drop of water to free the microfilariae and the preparation is examined under the low power of the microscope.

**Prognosis** The prognosis of onchocerciasis is good if the infection is detected early and adequately treated.

**Treatment** Surgical removal of the worm containing nodules using a local anesthetic is the method of choice. Diethylcarbamazine (Hetrazan) 1 to 2 mg per kg of body weight three times a day for two to three weeks is effective against the microfilariae but not against the adult worms. Marked ocular and orbital inflammation and other allergic manifestations frequently result from the rapid destruction of microfilariae; therefore initial total daily doses of 25 mg of diethylcarbamazine accompanied by an antihistaminic should be used. Cortisone or prednisone given a day before and during the first four days of Hetrazan therapy reduces the allergic reactions. Improvement of ocular symptoms and skin lesions usually follow this chemotherapy. Suramin (Bayer 205) kills the adult worms and the microfilariae gradually die off in several months. Suramin is given intravenously 1 gm weekly for five injections. The patient should be under constant medical supervision as severe reactions may be produced.

**Prevention** Avoidance of the vector flies is impractical as a preventive measure against onchocerciasis because the fly is a daytime biter. Repellents should be used by those working out of doors in endemic areas. Treatment of breeding places of the flies with larvicides has met with considerable success in Mexico and Guatemala.

## Dracunculosis

(Guinea Worm, Fiery Serpent)

**Etiology** Dracunculosis is caused by *Dracunculus medinensis* which inhabits the subcutaneous tissues and body cavities of man. It characteristically produces ulcers of the feet and legs.

**Life Cycle** The gravid female worm which grows to a meter in length migrates to the skin, especially to such parts as the legs and feet, which come in contact with water. The worm penetrates the subcutaneous tissues and produces a cutaneous blister which ulcerates. When the ulcer comes in contact with water the worm discharges large numbers of larvae. These larvae are ingested by water fleas of the genus *Cyclops* which migrate into its hemocoel cavity and mature. When man or other susceptible mammalian hosts drink water containing infected *Cyclops* they acquire the infection. Approximately a year is required for the complete development of the adult worm.

**Geographical Distribution** Dracunculosis is an important medical problem in India and the Middle East. It is locally important in Iran, Afghanistan, Turkestan, Egypt and Central Africa. Stoll estimates that 48,000,000 persons harbor the parasite. The disease is associated with dry climates where there is a concentration of water supplies in step wells or reservoirs in which there is a good opportunity for *Cyclops* to become infected. Arms, feet and legs of infected persons come in contact with drinking water sources into which the larvae are shed.

**Symptoms** The symptoms of dracunculosis appear with formation of the skin blister and consist of varying degrees of urticaria, nausea, vomiting, diarrhea, dyspnea and giddiness. There is a moderate eosinophilia. It is believed that these symptoms are due to the absorption of toxins excreted by the worms to form the blister. The symptoms suggest an allergic reaction and are amenable to treatment with epinephrine. Bacterial contamination of the ulcer may produce cellulitis and subcutaneous abscesses. Joints may be involved and permanent impairment may result. Bacterial infection is common when worms are mechanically extracted by the patient under the usual septic conditions.

slide-coverslip preparation of an emulsion of stool in water or saline. Various methods developed for estimating the number of worms in the intestine are valuable in surveys of population groups in order to determine the clinical importance of the disease in such groups. These methods, however, are not necessary in clinical practice since all persons harboring hookworms, no matter how few in number, should be treated.

**Treatment.** Preparation for anthelmintic treatment is important but it should not be overdone. The patient should have a liquid evening meal without fats or alcohol. If the patient is constipated a thorough cleansing enema is indicated. Anti-hookworm drugs should be given early in the morning and breakfast should be omitted. Food should be omitted for 4 to 5 hours and alcohol for 24 hours after treatment.

**Tetrachlorethylene** is the drug of choice for the treatment of hookworm as it is safe, effective and cheap. Millions of patients, many of them anemic and cachectic, have been treated with this drug. The several reports of untoward effects of tetrachlorethylene relate to giddiness, inebriation and rarely loss of consciousness. The only reported death was in an extremely debilitated and emaciated beggar in India. Carr and his associates reported the administration of 591,000 hookworm treatments with tetrachlorethylene without untoward effects other than occasional giddiness and drowsiness. Patients with hemoglobin as low as 15 gm per 100 ml of blood, massive edema and cardiac failure have been given the full dose of the drug without untoward happenings. The adult dose of tetrachlorethylene is 5 ml in gelatin capsules mixed with a little water or with a little sugar. Children are given 0.06 ml per pound of body weight. No purgation should be employed. One treatment will remove approximately 90 per cent of the *Necator*. A stool examination should be made two weeks after treatment and the medication repeated if necessary. If an *Ascaris* infection is present with the hookworms, *Ascaris* should be removed by piperazine before treatment for hookworms is given because tetrachlorethylene may stimulate *Ascaris* to migrate or produce intestinal obstruction.

**Hexylresorcinol** in crystalline form in specially prepared hard gelatin capsules will remove 60 to 70 per cent of the *Necator*. The adult dose is 1.0 gm. The dose for children is 0.1 gm for each year of age up to 10. The advantages of this drug

are that it is nontoxic and that it will remove *Ascaris* as well as hookworm. The crystals will burn the mouth if the capsules are chewed and the drug combines with protein and is soluble in fat so that food must be avoided for twelve hours before and four hours after treatment. Oil of *chenopodium* and carbon tetrachloride are both effective against hookworm but because of their toxicity they are not recommended.

The recovery from the symptoms of hookworm disease and the return to normal hemoglobin levels are especially slow in persons on a diet low in animal protein and iron. Iron therefore should be given in large amounts. The recommended daily dosage is 1.0 gm of ferrous sulfate (exsiccated) in capsules or 6.0 gm of ferric ammonium citrate in a 50 per cent solution. These preparations should be given in three divided doses after meals. It is best to start with smaller doses in order to avoid intolerance. Children should receive doses in proportion to their weight. This treatment produces rapid stimulation of reticulocytes and increase of hemoglobin and erythrocytes with rapid general improvement of the patient. Liver extract is of no value except for its iron content. The diet should be abundant and well balanced but this alone will not cause rapid improvement unless it has a high iron content.

**Prevention.** The prevention of hookworms consists of ensuring the sanitary disposal of human excreta. Since the hookworm larvae are unable to migrate vertically to any height, the deposition of excreta in a pit privy or a bored hole latrine is sufficient to prevent infection. The wearing of shoes will aid in the prevention of infection but local customs and cost often preclude their use. Treatment, though of great value to the patient, may be only of temporary value if reinfection can take place.

tissues sometimes even of the brain and free fluid in the serous cavities

**Symptoms** The larvae in penetrating the skin produce lesions which are called ground itch. These consist of maculo papules which become small vesicles. They are often confluent and rupture discharging serous fluid. They are surrounded by local erythema and swelling. Itching is severe. The commonest site is on the feet particularly between the toes but in miners it may be on the arms legs or buttocks. A creeping eruption type of lesion may be produced. Regional lymph nodes are often enlarged especially if secondary infection takes place.

The larvae in passing through the lungs may produce bronchitis if a heavy infection occurs at one time. It may be accompanied by fever. It has been noted particularly among miners.

The worms feed mainly on blood of which they are wasteful only fluid constituents being absorbed. Most of the ingested material is rapidly excreted through their anus. Hookworms ingest from 0.026 to 0.22 ml of blood daily. *Ancylostoma* consumes more blood than *Necator*. In heavy infections the worms individually consume less blood than in light infections. Although a hemolytic toxin has been demonstrated in extracts of hookworms it has not been shown that such a toxin contributes directly to the anemia or other symptoms.

**Very light infections** usually produce no recognized symptoms but elimination of the worms sometimes increases the vigor or accelerates normal development in children. Mild cases show slight pallor of the skin with a yellow tinge dryness of the skin with decreased perspiration some times slight abdominal discomfort slight cardiac palpitation on exertion slight weakness of the muscles and distaste for work. The appetite may be increased. Bowel movements are usually normal. Such cases usually show 4 000 000 to 5 000 000 erythrocytes per cu mm a hemoglobin concentration between 9 and 12 gm per 100 ml and varying degrees of eosinophilia.

**Moderately severe cases** show an exaggeration of these symptoms. The hair is dry and lusterless the expression of the face is dull there may be general itching of the skin the appetite may be voracious and the patient may eat earth or other mineral material although he rarely admits this. The tongue shares in the general

pallor and may show atrophy of the papillae. The bowels are usually constipated but there may be irregular intervals of diarrhea. The heart shows slight hypertrophy the pulse is rapid and often weak and a hemic systolic murmur is usually heard over the precordium. Electrocardiographic studies indicate that there is no change in the cardiac conduction mechanism. There is usually dyspnea on exertion. There may be dizziness tinnitus and headache. Weakness is marked fatigue is rapid and movements are slow. There may be a slight amount of albumin in the urine with or without a few casts. There may be edema of the feet. The blood contains 3 000 000 to 4 000 000 erythrocytes per cu mm. The hemoglobin is between 40 and 90 gm and eosinophilia is usually present.

**Severe cases** show further intensification of the anemia and cardiac dilatation. Weakness and stupor are apparent. Edema may involve the entire body including the face and the serous cavities and cardiac insufficiency may be present. Slight exertion causes severe dyspnea. The reflexes may be abolished and paresthesias are present. The skin is very dry. The appetite may be enormous or poor with associated pica. The stomach may become dilated and nausea and vomiting are frequent. Diarrhea may predominate over constipation. The stools do not contain gross blood but occult blood is readily found. The urine may show albumin and casts. These patients show between 1 200 000 and 3 000 000 erythrocytes per cu mm and 20 to 40 gm of hemoglobin. The color index sometimes exceeds 1. Eosinophilia is usually present.

In addition to these symptoms hookworm disease retards general development. Puberty is often delayed and if it occurred before infection took place sexual development may recede. The age of the patient may appear five to ten years less than it actually is. Mental development is proportionately retarded. In adults impotence may occur in men and menstruation may cease in women.

**Diagnosis** The most important element in the diagnosis of hookworm is to keep the disease in mind in the presence of symptoms and to examine routinely the feces of every patient in areas where the disease might be present. The final diagnosis of hookworm infection is based entirely upon the demonstration of ova in the stools. The simplest method is by a

fertile *Ascaris* or hookworm eggs and result in unnecessary anthelmintic therapy

## Hirudinea

### Hirudiniasis

#### (Leech Infestation)

Hirudiniasis or leech infestation may be acquired from exposure to infected lakes ponds or ditch waters and damp tropical forests. Leeches vary from 3 mm in length when the immature form attaches to man to 10 cm when they are fully grown. The mouths of some leeches are provided with cutting jaws. Their salivary gland secretion prevents the coagulation of blood so that the wound continues to bleed after they have detached themselves.

External hirudiniasis is due to both land and aquatic leeches which attach themselves to the skin of man and beast and suck blood. They may invade the nostrils. The wound is usually painless until the engorged leech drops off and the oozing of blood continues. Land leeches found in Asia India the Philippines Australia and South America climb shrubs from which they drop on man in numbers. The numerous wounds may result in considerable blood loss. Secondary bacterial infection and ulceration of the wound are not uncommon. Leeches should be removed with care lest the animal's jaws be left in the wound. Strong salt solution vinegar dropped on the site of attachment or a match flame applied to the worm will cause it to relax when it may be easily removed. The wound should be washed with an antiseptic solution the flow of blood stopped and a sterile dressing applied.

Internal hirudiniasis is most commonly caused by accidental ingestion of small immature leeches in raw drinking water. They become attached to the buccal mu-

cosa epiglottis pharynx upper esophagus nasopharynx vocal cords and trachea. The most notorious species of leech involved is the aquatic leech *Limnatis nilotica* of fresh water ponds lakes and streams of Mediterranean countries. As they grow they produce painful and dangerous obstruction of passages with epistaxis hemoptysis and hematemesis at times leading to considerable loss of blood. There may be continuous coughing hoarseness aphonia pain in the nasal cavity throat and chest dyspnea and suffocation difficulty in swallowing and nausea. Persons wading or bathing in infected water may suffer infestation of the urethra urinary bladder or vagina. Leeches lodged in the upper respiratory passages may be cocainized and removed by gentle traction. If leeches are attached to the posterior pharynx larynx trachea or bronchi the patient is placed in the Trendelenburg position before attempting to anesthetize and remove them. Otherwise they may fall further into the respiratory tract and cause suffocation. For leech infestation of the genitourinary tract irrigation with strong salt solution has proved of value in killing and removing the leeches. Impregnation of cloths with repellents will protect against external infections and the boiling of drinking water will prevent internal infections.

## Arthropods and Human Disease

The arthropods which include the insects spiders ticks mites scorpions centipedes and crustaceans are medically important as causative agents of disease

mechanical carriers of pathogenic microorganisms and necessary intermediate hosts in which multiplication and development take place

## Creeping Eruption

(Cutaneous Larva Migrans)

**Etiology** Creeping eruption is a dermatitis characterized by serpiginous intracutaneous lesions. Among the nematode larvae the hookworm *Ancylostoma braziliense* is most commonly incriminated although other species of hookworms *A. caninum*, *Uncinaria stenocephala* and *Necator americanus* occasionally are the etiological agents. *Strongyloides stercoralis* may also cause similar lesions. Another nematode with larvae that cause creeping eruption is *Gnathostoma spinigerum* found in the Orient. Creeping eruption due to fly larvae (maggots) is a dermal myiasis due primarily to the larvae of the horse bot *Gasterophilus*.

**Geographical Distribution** *Ancylostoma braziliense* has a wide distribution in dogs and cats and the infection of man has a similar distribution. In the United States the infection is prevalent on the eastern seaboard from Virginia to Florida and in the Gulf States. Sea bathers who bask in the sun, plumbers who come in close contact with larval infected soil and children who play in sandboxes that are open to cat and dog pollution are most commonly infected.

**Symptoms** The infectious filariform larvae of *A. braziliense* live in moist loamy or sandy soil where infected dogs and cats have defecated. The larvae which are approximately 300  $\mu$  in length penetrate the skin of man but they are either unwilling or unable to penetrate the blood vessels and complete the usual larval migration to the intestine. They remain in the skin. The feet, legs and hands are most commonly involved but infection of any portion of the body exposed to infected soil may occur. Plumbers are most commonly infected on their knees, elbows, buttocks and shoulders. There is an intense pruritus at the point of larval entry and a red papule develops. Within a day or two as the larva migrates intracutaneously a narrow slightly elevated erythematous serpiginous lesion develops at the rate of a centimeter or two per day. Vesicles form along the course of the lesion and scale off. The lesion causes severe itching especially at night and scratching may lead to secondary infection. The larvae migrate for two to eight weeks before dying and at the site of their demise a papule is formed. Some patients develop a transitory patchy infiltration of the lungs accompanied by an eosinophilia of the blood as high as 51 per cent and in the sputum

as high as 90 per cent. This Loeffler's syndrome is the result of pulmonary migration of the larvae, their destruction and an allergic reaction of the host.

The lesions of creeping eruption due to *Gnathostoma* and *Gasterophilus* are cutaneous and subcutaneous and produce migratory swelling.

**Treatment** The treatment of choice for creeping eruption due to *A. braziliense* is the use of an ethyl chloride spray. An area of 2 cm in diameter at the active end of the lesion where the larvae reside is frozen for two to four minutes. The spraying may be supplemented by cold wet antiseptic dressings. Injections of Fuadin into the infected areas or intramuscularly have been used with equivocal success. The piperazine compounds Hetrazan and Antepar by mouth have also been used. Secondary bacterial infection should be treated with suitable antimicrobial drugs.

Surgical removal of *Gnathostoma* and *Gasterophilus* larvae and other fly larvae is the treatment of choice of these parasites.

**Prevention** The control of creeping eruption of hookworm origin consists in avoiding skin contact with soil which has been contaminated with dog or cat feces, keeping animals off beaches and from beneath houses where plumbers may work and anthelmintic treatment of dogs and cats will prevent contamination of the soil. Children's sandboxes should be covered when not in use. Skin infection with *Necator* and *Strongyloides* can be prevented by proper disposal of human excreta. *Gnathostoma* is acquired by the ingestion of raw fish containing the larval stage of this worm.

## Heterodera Radicicola

*Heterodera radicicola* is a small nematode parasite of the roots and stems of vegetables including radishes, turnips and celery. When the adult female or eggs are consumed with their vegetable host the eggs of the parasite are found in man's stool. The eggs may be mistaken for in

DDT and 1 per cent benzene hexachloride or pyrethrum powder may be substituted for it. The secondary pyoderma should be treated with antibiotics.

**Prevention** The prevention of lousiness consists primarily in personal cleanliness and avoidance of infected persons, bedding and wearing apparel. Fortunately the lice of domestic animals are not attracted to man.

## Fleas

*Pulex irritans* is primarily a human flea. The fleas of the cat and dog (*Ctenocephalides*) and of the rat and mouse (*Xenopsylla*) also frequent man. They usually migrate over the body until a tight garter or belt obstructs their passage and here they proceed to suck blood. Individuals vary greatly in their reaction to the salivary secretions of fleas. Some are unaffected. In those who are severely irritated, raised, red, edematous lesions are produced. Local application of camphorated phenol in mineral oil is palliative. The control of fleas usually requires the destruction of the fleas of man, dog and cat in the home. Vacuum cleaning the rugs, scrubbing the floors and removing debris will eliminate adult fleas as well as eggs and larvae. Insecticidal sprays may also be used such as a 5 per cent DDT in oil. The dog yard, kennel and beds of cats should be sprayed or dusted with DDT. The practice of rubbing DDT into the fur of these animals is very effective. Care must be taken with cats because they may lick off the dust which is somewhat toxic to them.

The chicken flea (*Echinophaga*) called the stick tight flea attacks man especially children. It can be controlled by spraying the chicken house and yard with DDT.

The chigoe or sand flea *Tunga penetrans* is primarily a parasite of the pig but it frequently infests man and also dogs, cats and rats. This small flea approximately 1 mm in length burrows into the skin of the feet between the toes and under the nails. Here the female nourished by blood grows to pea size. The wound is painful, ulcerates and becomes infected with various bacteria. **Treatment** consists of surgical removal of the flea and aseptic dressing of the wound until it heals. Dusting the feet and socks with a 2.5 per cent DDT powder will prevent infection.

## Chiggers, Redbugs or Harvest Mites

These minute mites attack men only during their larval stage. *Eutrombicula alfreddugesi* is the common species found in the United States; other species which make man miserable are found in most parts of the world.

The redbug larva attaches to the skin and secretes a saliva which by a process of digestion creates a tube called a stylostome in the skin. The dissolved tissue is sucked up for food. In twelve to twenty-four hours as this process proceeds, an intense itching is produced which continues for several days. A small red macule is formed at the site of attachment of each mite and hundreds may cover the feet, legs, scrotum and other parts of the body. The diagnosis is made by the history of exposure in endemic areas, the intense itching and finding the small red orange six-legged larvae attached to the skin. Benzene hexachloride (Kwell) or benzyl benzoate ointment is suggested for treatment. Camphorated phenol in mineral oil is palliative. **Prevention** consists in dusting DDT powder into clothing and wearing tightly woven clothing, trouser cuffs should be stuffed into the shoe tops.

## Myiasis

### (Maggot Infestation)

A number of species of flies deposit their eggs on food, especially overripe fruits, vegetables and decaying meat. Man accidentally ingests the eggs and larvae and intestinal myiasis results. Fortunately the gastrointestinal juices usually are fatal to the larvae and they are passed in the feces. The cheese skipper, a fly maggot, is not an unusual part of the gourmet's repast. Nausea, vomiting, abdominal cramps and diarrhea may be caused by intestinal myiasis. Fly larvae that are found in stools brought to the laboratory for various examinations are often the result of fly eggs being deposited on the unprotected stool as it awaits transportation to the laboratory.

A number of flies of the genera *Callitroga*, *Sarcophaga* and others which normally deposit their eggs or larvae on decaying flesh of dead animals will lay their eggs on infected wounds in odoriferous

## Scabies

### (Sarcoptic Itch)

The *Sarcoptes scabiei* or itch mite is approximately 0.35 mm in length. The female mite excavates tortuous tunnels in the skin and here lays her eggs and deposits her irritating excreta. The young establish themselves in lateral burrows or come out of the mother's tunnel and develop their own. The adults live about four weeks. Although there is a new generation every three weeks, the population does not increase to the astronomical numbers theoretically possible. The average number of adult females in an infested person is 12 and few harbor more than 30. Scabies is world wide with a predilection for the poor, crowded and unwashed. The lesion is a reddish elevated tract on the surface of the skin with translucent vesicular swellings along its course. The mites most commonly invade the skin between the fingers or on the hands and wrists. They also invade the skin of the elbows, groin, breast, external genitalia, feet, shoulder blades, small of the back and other areas. Sensitization plays an important part in the symptomatology for the intense itching which characterizes the disease does not begin until a month after the initial infection. In seven to sixteen weeks after infection a maximum mite population of 50 to 500 may be reached and during this period the irritation increases until it disturbs the sleep and becomes continuous and unbearable. Scratching leads to secondary bacterial infection and impetigo may develop. The reaction to reinfection is prompt within twenty-four hours; there is marked local irritation and redness.

**Diagnosis** The lesions and their distribution are characteristic. It may be possible to make a definite diagnosis by removing a mite or a portion of one from its burrow with a needle. Skin scrapings should be cleared in 10 per cent potassium hydroxide for microscopic examination.

**Treatment** The treatment of scabies is most successfully carried out with an ointment or vanishing cream (Kwell) containing 10 per cent benzene hexachloride. To ensure cure the whole body from the neck down should be treated. Cannon and McRae cured 61 per cent of their patients with one application, 97 per cent with two treatments and the remaining 3 per cent with three applications. Benzyl benzoate lotion or emulsion is also very effective.

**Prevention** The prevention of scabies consists in avoiding contact with infected persons, soiled bed linen and public towels. Infested bed mates should be treated. The mange mites of dogs, cats and other mammals may invade man's skin but apparently cannot continue their life cycle there. Pet dogs and cats with mange should be treated.

## Pediculosis

### (Head, Body and Pubic Lice)

Man provides food and shelter for two genera of lice. *Pediculus humanus* var. *capitis* infests the head and *P. humanus* var. *corporis* the body and clothing. *Phthirus pubis* usually lives in the pubic area but on occasion extends its range to the axilla, chest hairs and even the eye brows and eyelashes. The eggs, called nits, of the head and crab louse are attached to the hairs of the host while the body louse attaches its eggs to the clothing of the host. All three lice suck blood for nourishment. Their saliva injected during feeding and probably their excreta are responsible for the irritating roseate papular dermatitis. Scratching may lead to secondary bacterial infection with crusts and matted hair. Induration and pigmentation of the skin may be present in severe infestations. Enlargement of the lymph nodes, especially the postauricular group, is present in severe capitis infestation. *Phthirus pubis* infestation of the eyelashes leads to blepharitis. The cutaneous lesions and characteristic scratching suggest the diagnosis which is confirmed by finding the eggs or adults. The latter can be combed out of the hair with a fine toothed comb.

**Treatment** In the treatment of head lice an ointment of 10 per cent benzene hexachloride in vanishing cream (Kwell) should be rubbed on the scalp thoroughly. This treatment is also effective for pubic lice when the ointment is massaged into the skin of the infested area. Lice and eggs should be removed individually from the eyelashes. Body lice are destroyed by sterilizing the clothing by heat and using the ointment on infested areas of the body. A 10 per cent DDT in pyrophyllite dusted onto the head, body and clothing without undressing is highly effective. Lice in Korea and Egypt have developed resistance to

DDT and 1 per cent benzene hexachloride or pyrethrum powder may be substituted for it. The secondary pyoderma should be treated with antibiotics.

**Prevention** The prevention of lousiness consists primarily in personal cleanliness and avoidance of infected persons, bedding and wearing apparel. Fortunately the lice of domestic animals are not attracted to man.

## Fleas

*Pulex irritans* is primarily a human flea. The fleas of the cat and dog (*Ctenocephalides*) and of the rat and mouse (*Xenopsylla*) also frequent man. They usually migrate over the body until a tight garter or belt obstructs their passage and here they proceed to suck blood. Individuals vary greatly in their reaction to the salivary secretions of fleas. Some are unaffected. In those who are severely irritated, raised, red, edematous lesions are produced. Local application of camphorated phenol in mineral oil is palliative. The control of fleas usually requires the destruction of the fleas of man, dog and cat in the home. Vacuum cleaning the rugs, scrubbing the floors and removing debris will eliminate adult fleas as well as eggs and larvae. Insecticidal sprays may also be used, such as a 5 per cent DDT in oil. The dog yard, kennel and beds of cats should be sprayed or dusted with DDT. The practice of rubbing DDT into the fur of these animals is very effective. Care must be taken with cats because they may lick off the dust, which is somewhat toxic to them.

The chicken flea (*Echinophaga*) called the "stick tight flea" attacks man, especially children. It can be controlled by spraying the chicken house and yard with DDT.

The chigoe or sand flea *Tunga penetrans* is primarily a parasite of the pig but it frequently infests man and also dogs, cats and rats. This small flea, approximately 1 mm in length, burrows into the skin of the feet between the toes and under the nails. Here the female, nourished by blood, grows to pea size. The wound is painful, ulcerates and becomes infected with various bacteria. Treatment consists of surgical removal of the flea and aseptic dressing of the wound until it heals. Dusting the feet and socks with a 2.5 per cent DDT powder will prevent infection.

## Chiggers, Redbugs or Harvest Mites

These minute mites attack men only during their larval stage. *Eutrombicula alfreddugesi* is the common species found in the United States, other species which make man miserable are found in most parts of the world.

The redbug larva attaches to the skin and secretes a saliva which by a process of digestion creates a tube called a stylostome in the skin. The dissolved tissue is sucked up for food. In twelve to twenty-four hours as this process proceeds, an intense itching is produced which continues for several days. A small red macule is formed at the site of attachment of each mite and hundreds may cover the feet, legs, scrotum and other parts of the body. The diagnosis is made by the history of exposure in endemic areas, the intense itching and finding the small, red-orange, six-legged larvae attached to the skin. Benzene hexachloride (Kwell) or benzyl benzoate ointment is suggested for treatment. Camphorated phenol in mineral oil is palliative. Prevention consists in dusting DDT powder into clothing and wearing tightly woven clothing, trouser cuffs should be stuffed into the shoe tops.

## Myiasis

### (Maggot Infestation)

A number of species of flies deposit their eggs on foods, especially overripe fruits, vegetables and decaying meat. Man accidentally ingests the eggs and larvae and intestinal myiasis results. Fortunately the gastrointestinal juices usually are fatal to the larvae and they are passed in the feces. The cheese skipper, a fly maggot, is not an unusual part of the gourmet's repast. Nausea, vomiting, abdominal cramps and diarrhea may be caused by intestinal myiasis. Fly larvae that are found in stools brought to the laboratory for various examinations are often the result of fly eggs being deposited on the unprotected stool as it awaits transportation to the laboratory.

A number of flies of the genera *Callitroga*, *Sarcophaga* and others which normally deposit their eggs or larvae on decaying flesh of dead animals will lay their eggs on infected wounds in odoriferous

discharges. *Chrysomya*, *Wohlfartia* and others deposit their eggs and larvae on fresh wounds and feed on living tissues. Vomitus or odors from natural cavities with a discharge attract them to the mouth, nose, ear or vagina. The damage done by a heavy infestation may be extensive, disfiguring and even fatal. Sheep and horse bot flies, *Hypoderma*, *Oestrus* and others may lay their eggs in the eye, nose and mouth of man. Flies occasionally lay their eggs on healthy persons, especially babies sleeping out of doors, and the larvae penetrate the skin. Boil-like lesions may be produced. *Dermatobia* larvae penetrate the skin of the body, face and neck when insects upon which the fly fastens its eggs feed on man.

A cutaneous creeping eruption grossly similar to that produced by *Ancylostoma braziliense* is caused by the fly larvae of *Gasterophilus*, the horse warble.

Treatment consists of surgical removal of fly larvae when possible. Irrigation of infested cavities with chloroform aids in the removal of larvae. Tetrachlorethylene and purgation are useful in intestinal myiasis.

Prevention consists of avoiding spoiled food on which fly eggs may have been laid, bandaging open wounds and protecting sleeping babies against flies.

## Venenating Arthropods

(Centipedes, Scorpions, Spiders, Ticks, Wasps, Ants, Blister Beetles, Caterpillars)

The venenating arthropods which injure man by bites, stings and contact include centipedes, scorpions, spiders, ticks, bees, wasps, ants, blister beetles and the caterpillars of moths and butterflies.

Centipedes have a pair of hollow "fangs" through which a venom is introduced into the victim when they penetrate the skin. Small species produce only local inflammation. The large tropical forms cause local necrosis at the site of bite, lymphangitis, fever, vomiting and headache.

Scorpions are armed with a single curved caudal stinger with which they inject their neurotoxic venom. The smaller species produce a painful inflammation at the site of the sting. The larger species cause painful local inflammation, salivation, nausea, vomiting, headache, dizziness, perspiration, rapid respiration, weakened pulse and pancreatitis. Sugar is frequently found in the

urine and albumin may be present. Fatal stings usually among small children are characterized by convulsions, coma and death from respiratory failure or pulmonary edema. Treatment consists of a tourniquet on the injured member. An ice pack will slow the dissemination of the toxin. Specific antivenin is recommended. Subcutaneous injection of Novocaine and epinephrine at the site of the sting relieves the pain. Phenobarbital in massive doses is helpful in stopping convulsions. Spraying DDT or benzene hexachloride on the haunts of scorpions will reduce their numbers.

Spiders use venom to paralyze their prey. Several species can penetrate man's skin, but of these only a few can cause serious symptoms. The bite of the large tarantulas of the tropics produces mild to severe pain in man. *Loxosceles laeta* of South America causes extensive tissue sloughing at the site of its bite. Bites of *Lactrodectus mactans*, the black widow spider, may cause severe symptoms. The female black widow spider is approximately 13 mm in length and is completely black except for variable orange-red markings on her body. The diagnostic marking of the female is an hourglass-shaped marking on her ventral surface. This species is found from southern Canada to Chile, and other species are found in Europe and other parts of the world. The spider inhabits lumber and junk piles, camps, basements and outbuildings. Outdoor privies lead as a source of bites and the buttocks and penis bear the brunt of the attacks.

Symptoms. The venom injected is probably a toxalbumin and it affects the nerve endings. It is not hemolytic. Frequently the bite is unnoticed but it may be painful. An area of pallor, reddening or urticaria may mark the site. Systemic symptoms vary and are usually much more severe in children than in adults. The patient becomes weak, dizzy, nauseated and perspires profusely. Boardlike rigidity and spasm of the abdominal muscles, fever and leukocytosis simulate the presence of an acute abdominal disease. The blood pressure rises and breathing becomes labored. Profound shock, delirium, urinary retention and in small children convulsions may lead to death within forty-eight hours. Recovery is rapid as the toxin is excreted and is accompanied by slight fever, diaphoresis and leukocytosis.

Diagnosis. The history of spider bite if elicited is most valuable and the gradual spread of the muscular pain is of assistance.

in separating it from acute surgical abdomen

**Treatment** The patient should be placed in bed and given intravenously 10 ml of a 10 per cent calcium gluconate solution. Antivenin is available and of value. Hot baths may relieve pain and morphine may be required for analgesia. Corticotropic and adrenal corticosteroids afford prompt symptomatic relief. Neostigmine and atropine are both useful in relieving muscular spasm.

**Prevention** Thorough spraying or dusting the habitats of predilection of *Latrodectus* with DDT affords considerable protection. Special attention should be given to outdoor privies.

**Ticks** introduce a poison into the skin along with their saliva when they feed on man. Fever, ascending motor paralysis and death through cardiac and respiratory failure may result. The most serious disease is produced by the engorging female tick on the back of the neck or at the base of the skull. The condition is most common in females as their long hair hides the attached tick. Recovery takes place in one to six days after the tick is removed or falls off. Gentle traction on the tick rather than a sudden jerk is recommended for removal of the ticks from the skin. Freezing the ticks with ethylchloride or applying a lighted cigarette to their rear assists in their removal intact.

**Bees, Wasps and Ants** Bees and wasps have a posterior sting apparatus, the modified ovipositor through which the venom is injected into the skin. Usually local inflammation and pain are the only symptoms and they disappear after a few hours. Stings from a swarm of bees may be rapidly fatal. Hypersensitive persons may experience a severe reaction from a single bee sting in some instances with fatal termination. Such persons manifest symptoms of anaphylactic shock with respiratory and cardiac impairment, edema and urticaria. Prednisone 30 mg. along with a quick acting antihistamine should be given immediately after exposure and this dose repeated in fifteen to thirty minutes if symptoms appear. Epinephrine is also indicated. Patients who have had serious reactions to bee stings should be desensitized by a course of bee antigen to prevent subsequent serious reactions. An antihistamine may relieve discomfort. Several species of ants produce a painful sting. The "fire ant" which is spreading in the southern United States causes a fiery sting and pruritic vesicles.

**Blister Beetles** of which the Spanish fly is a well known example secrete a vesicating substance, cantharadin, which on contact with the skin produces a blister. Some of these acute vesicating lesions heal slowly. Soothing alkaline lotions are palliative.

**Caterpillars** of moths and several butterfly species have hollow venom-containing hairs. Poisoning may be caused by contact with the caterpillars, their nest or their wind-blown hairs. The pain from the lesion produced by a poisonous caterpillar falling on the skin may be excruciating. A vesicular erythema with a localized area of necrosis develops. Wind-blown hairs produce a prickling and burning sensation of the skin and a severe inflammation of the eye. Calamine lotion or ammonia solutions are palliative.

## Arthropods as Mechanical Carriers of Disease

The common housefly and its relatives, the stable fly, green bottle, blue bottle, blow fly and flesh fly, breed and feed on human and animal feces and garbage. Typhoid fever, bacillary dysentery, infant diarrhea, amebiasis and cholera may be transported on the fly's body from the feces of man to his food. The pathogenic organisms are also found in the vomitus and feces of flies. Flies of the genus *Musca* are attracted to sores and food remnants on children's faces and participate in the transmission of trachoma and purulent conjunctivitis. Flies have also been found to harbor the virus of poliomyelitis. It is possible that fecal feeding flies may transmit infectious hepatitis. The stable fly contaminated with horse manure may introduce tetanus and anthrax spores into the skin. Small flies called eye gnats have been incriminated in epidemics of acute conjunctivitis or pink eye and may transmit trachoma.

**Control of flies** in addition to sprays of 10 per cent DDT in kerosene and other sprays, assists in the prevention of fly breeding. Garbage cans should be tightly covered and the garbage when collected incinerated or disposed of in a suitable land fill. Barnyard manure should be protected against flies. Houses, food cabinets and milk producing barns should be screened. Outdoor privies should be con-

structed in such a manner as to prevent the access of flies to the feces and the pit should receive generous application of DDT spray quick lime or crude oil

Cockroaches, through their contact with filth and food may transmit pathogenic intestinal bacteria certain viruses and protozoan cysts Cleanliness in the kitchen and protection of stored foods are essential in the control of cockroaches Closing crevices around pipes running from floor to floor in apartment houses will help to keep the neighbors cockroaches at home Ten per cent DDT powder or 1 per cent benzene hexachloride powder spread about the haunts of cockroaches is an effective control measure

Bedbugs (genus *Cimex*) are reddish brown wingless and have a disagreeable odor The bite of the bedbug ordinarily produces red itching wheals Sensitive persons experience considerable urticaria but some persons show no reaction Although the blood sucking habits of the bedbug would seem to fit it ideally for disease transmission and although man universally dislikes this insect and desires to incriminate it in disease transmission all attempts to do so have failed Bedbugs have been infected in the laboratory with numerous organisms pathogenic for man but apparently in nature they do not spread them to any extent A 5 per cent emulsion of DDT or 1 per cent benzene hexachloride

spray on infested bed frames furniture and wall crevices will control this insect

## Arthropod Intermediate Hosts

The diseases for which arthropods serve as vectors and hosts in which the pathogenic organisms multiply or undergo development are considered in other sections of this book

## DISEASES OF UNPROVED ETIOLOGY

### Sarcoidosis

(Hutchinsons Besniers Boecks Heer  
fordts Schaumanns Junglings Syn  
drome or Disease Benign Lympho  
granulomatosis Uicoparotid  
Fever Lupus Pernio)

**Definition** Sarcoidosis is a systemic granulomatous disease or possibly a group of diseases of unknown etiology. The disease most often involves lymph nodes, lungs, liver, spleen, skin and eyes, but any tissue or organ may be affected. The characteristic histological lesion consists of epithelioid cell tubercles with little or no necrosis. Clinical manifestations are dependent in large part upon the degree of functional alteration produced in a particular tissue or organ and are therefore subject to marked variation. Although the course may be characterized by acute clinical exacerbations or by spontaneous and complete recovery, persistence of indolent disease for years is seen more often. Less frequently the disease may follow an unremitting progressive course terminating fatally.

**Etiology** There is at present no general agreement as to a specific etiological agent in sarcoidosis. It is not unlikely that several etiological agents may produce diseases which are at present indistinguishable histologically from sarcoidosis. Indeed the close similarity of certain features of sarcoidosis and tuberculosis, histoplasmosis, coccidioidomycosis and berylliosis has prompted much of the etiological investigation to date. Moreover the ability of certain microbial agents, foreign bodies and chemicals to produce a lesion closely resembling the sarcoid tubercle has necessitated a clear distinction between the frequent occurrence of local sarcoid tubercles and the systemic disease.

Major interest until recently has centered on *Mycobacterium tuberculosis* as the causative agent. It has been postulated that sarcoidosis is either an attenuated form or a distinct clinical phase of tuberculosis. Support for this hypothesis is predi-

cated upon the occurrence of sarcoidosis as a noncaseating anergic tuberculosis in which rapid and complete bacillary destruction ensues. The release of tuberculin stimulates an immunological host response which results in the production of tuberculin neutralizing substances. As a direct consequence of these tuberculin neutralizing substances, relative tuberculin insensitivity is present; hence the concept of positive anergy. Weighing strongly against this concept are the normal survival of certain tubercle bacilli (BCG) in patients with sarcoidosis, the presence in similar frequency and amount of tuberculin neutralizing substances in normal subjects, and the demonstration that relative cutaneous hyposensitivity in sarcoidosis is not specific for tuberculin. Furthermore, recently demonstrated epidemiological inconsistencies between tuberculosis and sarcoidosis have removed tuberculosis from prominent consideration as an etiological agent in sarcoidosis.

Epithelioid cell granulomata may be produced in normal animals by injection of pine pollen or chemical fractions derived from pine pollen. An etiological role for pine pollen in clinical sarcoidosis is, however, not yet established.

Berylliosis has been noted to have many features in common with sarcoidosis, and the possibility that beryllium present in the soil is responsible for sarcoidosis has been given serious consideration. Foreign body reactions due to silica, quartz, talc, etc., may result in local sarcoid lesions, but no etiological relationship of these particulate materials to sarcoidosis has been established. Recently, however, calcareous spar has been isolated from lesions of sarcoidosis, and renewed interest in this component of certain soil types has occurred.

**Epidemiology** Sarcoidosis occurs at all ages from childhood to old age, the greatest number of cases being recognized between the ages of twenty and forty. The sexes are affected equally. There is no indication of communicability or an inherited predisposition, although the disease has occasionally occurred in siblings, identical twins, and household contacts.

Major clinical interest in sarcoidosis has centered in the United States England the Scandinavian countries France Switzerland and Germany yet the disease is believed to occur in all regions of the world. Sufficiently comprehensive and accurate prevalence data are not yet available for populations at large. An attack rate of 0.66 per 100 000 has been reported for the general population of Oxfordshire England. In the United States and Swiss military personnel however 2.1 and 13 cases of sarcoidosis respectively were recognized in each 100 000 surveyed. One might anticipate a higher incidence in military groups because of the age selection. Nevertheless these data probably represent falsely low attack rates for their respective populations since many cases of sarcoidosis might easily have escaped detection because of present inadequacies in mass diagnosis.

A striking geographical concentration of sarcoidosis in the southeastern United States was demonstrated in a study of the distribution by birthplace of military personnel with sarcoidosis of World War II. This distribution has been found to correlate with the occurrence of certain soil types. The similarity of this geographical distribution and that of urinary calculi has also been noted. A similar study of 1194 cases of sarcoidosis diagnosed at United States veterans hospitals between 1949 and 1954 not only confirmed the above geographical concentration but also extended the distribution pattern to the New England and North Central States. The correlation of this latter distribution with that of forested areas is impressive. The full epidemiological significance of these data is not yet clear but the predisposition of the American Negro to sarcoidosis was amply confirmed. Though all races are known to be affected by sarcoidosis a ratio of Negro to white cases of 18:1 and 12:1 was encountered for the military personnel and veterans respectively. In addition these studies also re-emphasize a universal finding: the higher incidence of the disease in those born in rural areas.

**Morbid Anatomy.** No single histological feature may be regarded as pathognomonic for sarcoidosis. A heterogeneous group of diseases or agents may simulate sarcoidosis or the local sarcoid lesion.

The epithelioid cell granuloma or tubercle the cardinal feature of the disease is a discrete concentric arrangement of elongated epithelioid cells. The size and development of the granulomas in a par-

ticular organ are often so similar that the pattern has been referred to as "monotonous." Giant cells of the Langhans and foreign body type are common and may contain inclusion bodies such as the asteroid or spiculated bodies and Schaumann bodies (round or oval noncrystalline concentrically laminated inclusions). Neither inclusion body is specific for sarcoidosis. As the sarcoid granuloma matures a fine rim of fibroblasts encircles the lesion. Necrosis is infrequent but when present is acellular central and fibrinoid in character. Caseation necrosis does not occur. Healing takes place primarily by fibrosis with subsequent formation of a dense scar as the tissue becomes compact and hyalinized.

**Pathological Physiology.** Constitutional manifestations are produced almost entirely through mechanical interference by epithelioid granulomas and fibrous scars with the normal function of a particular organ. Moreover the particular organ function which has been altered largely determines the seriousness of the disease: i.e. myocardial pulmonary central nervous system or ocular lesions may be of far greater consequence than extensively disseminated lesions in less critical tissue.

Involvement of peripheral lymph nodes is demonstrable by palpation or biopsy in almost all patients with sarcoidosis but rarely produces symptoms. Deep lymph node involvement is frequent but also is unlikely to cause symptoms. Enlarged hilar or peribronchial nodes may occasionally produce obstructive phenomena: atelectasis and possibly together with bronchial mucus membrane involvement stimulate cough.

**Pulmonary involvement.** Next to lymphatic tissue in frequency of involvement is characterized by infiltration of the interalveolar walls by the sarcoid granuloma which as it heals is replaced by fibrous tissue. Intervening normal lung parenchyma undoubtedly accounts for the paucity of pulmonary symptoms until an advanced stage is reached. The dense interalveolar scar tissue and reduction in the effective diffusing surface by sarcoid displacement of alveolar space make gas diffusion more difficult. This "alveolar-capillary" block accounts in large part for the dyspnea and cyanosis both of which may be initiated or exaggerated by exercise.

Involvement of the heart is usually a consequence of extensive pulmonary sarcoidosis and fibrosis leading to the subsequent development of cor pulmonale. Di-

rect invasion of the myocardium with displacement of myocardial fibers occurs in about 20 per cent of autopsied cases how ever and may lead to sudden death Thus myocardial damage in sarcoidosis may result in right ventricular enlargement progressive myocardial failure or conduction effects

Sarcoidosis of the liver is recognized by needle biopsy or at autopsy in approximately 65 to 75 per cent of cases yet clinical evidence of involvement of the liver is usually limited to hepatomegaly and rarely jaundice Splenomegaly is detected at autopsy in a similar percentage and also in the same frequency clinically as hepatomegaly (in about 20 to 25 per cent of cases) Secondary thrombocytopenic purpura Bant's syndrome spontaneous rupture hemolytic anemia hypersplenism and sensation of heaviness in the splenic area have all been attributed to sarcoidosis of the spleen

Although the most extensively described manifestation the relative frequency of cutaneous lesions in sarcoidosis has decreased because of the wider recognition of the systemic component of the disease The small and large nodules and the diffuse flat plaques occur in about 40 per cent of sarcoidosis Despite the many and varied appearances of the cutaneous lesions the histological picture is characteristic of that seen elsewhere The lesions may persist for prolonged periods only to heal without residue or as atrophic depigmented scars New emphasis has been placed upon the occurrence of erythema nodosum in sarcoidosis The frequent association with generalized lymphadenopathy in particular with massive bilateral hilar node enlargement has been noted recently

Iritis and iridocyclitis usually bilateral are the most common eye lesions The fate of these lesions is quite variable there may be spontaneous complete healing but permanent progressive damage frequently resulting in blindness may be the ultimate outcome Of the unfavorable results cataracts secondary glaucoma phthisis bulbi optic atrophy and corneal opacities are the more serious sequelae

Localization in bone is probably more common than is determined by roentgenographic studies Diffuse granulomatous infiltrations of the marrow may occur but only those leading to resorption of cancellous bone account for the reticular lace like pattern and punched out areas seen in the roentgenogram The cortex is rarely invaded and joint involvement is not com

mon External evidence of bone infiltration is usually limited to a mild painless fusiform swelling of the fingers extensive destruction with mutilation of the digits is infrequent

Sarcoidosis may involve any part of the nervous system Encephalitis convulsions and diabetes insipidus due to hypothalamic or pituitary lesions have been attributed to sarcoid lesions in the central nervous system Probably the most common lesion is Bell's palsy usually unilateral and transient in nature but sometimes followed by persistent facial nerve paralysis Several other cranial nerve lesions have been described Meningeal and cord lesions have been observed but are infrequent

Renal insufficiency may occur usually attributable to the hypercalcemia and consequent nephrocalcinosis seen in sarcoidosis Less frequently renal damage occurs as a direct result of sarcoid infiltrations

Symptoms Outstanding among the clinical features of sarcoidosis is the striking disparity between the mildness or absence of symptoms and the extensive involvement of the organs and tissues Nonetheless both constitutional reactions and local complaints referable to specific organ involvement usually occur at some time in the course of the disease They may become manifest singly in combination or in sequence making a concise clinical description difficult

Weight loss easy fatigability and malaise appear insidiously and may be accompanied by vague thoracic or abdominal complaints night sweats and low grade fever Fever is usually absent during the chronic stabilized phase of the disease and when present may be attributed to a secondary complication Nevertheless during exacerbations or in certain clinical forms of sarcoidosis such as uveoparotid fever a slight temperature elevation is frequent and in rare instances fever is the most prominent feature of the disease

Symptoms directly referable to specific organ involvement are expressed clinically in terms of functional impairment Most frequent are the symptoms related to involvement of the lungs intrathoracic lymph nodes skin and eyes

The mere presence of symptoms in pulmonary sarcoidosis signifies extensive involvement of the lungs Cough is mild transitory and intermittent but may become severe and persistent Sputum if present at all is nonpurulent and small in amount unless secondary infection or less frequently bronchiectasis appears as a complication

FIG 43 Asymptomatic onset of massive bilateral hilar and mediastinal lymphadenopathy (Courtesy Dr H S Weens)

Dyspnea initially mild and present only after exertion may reflect the advancing functional inroads of progressive diffuse pulmonary sarcoidosis. Pulmonary fibrosis, reduction of the alveolar diffusing surface by interalveolar granuloma and emphysema may further accentuate the dyspnea. In addition, cor pulmonale is a frequent consequence of the severe pulmonary damage and the symptoms of heart failure may be superimposed and often predominate. Other symptoms of pulmonary sarcoidosis are less common: mild chest pains are ill defined and may be the result of pulmonary hypertension. Pleuritic pain and pleural effusion are rare.

Ocular manifestations are commonly expressed in terms of difficulty in vision, although mild pain may occasionally be present. When severe pain occurs in ocular sarcoidosis, secondary conditions such as glaucoma usually are present.

An infrequent but well documented clinical expression of sarcoidosis is presented by the triad of uveoparotid fever, uveitis, relatively asymptomatic swelling of the parotid and other salivary glands and Bell's palsy. This triad is rarely seen, however, as the sole expression of sarcoidosis. An annoying symptom, dryness of the mouth, may occur as a consequence of interference with salivary gland secretory function. The acute phase of the disease, represented by uveoparotid fever, lasts from several weeks to a few months and is terminated by spontaneous regression. The ocular manifesta-

tions are the least likely to clear completely and tend to relapse or recur.

The physical examination often uncovers features which are highly suggestive of the disease. Peripheral lymph nodes are usually palpable at some period in the course of almost all patients. The nontender, firm, discrete, movable nodes infrequently exceed 3 cm in diameter and are most apt to be prominent early in the course of disease or during acute exacerbations. During the chronic, less reactive phase, the nodes may regress markedly. Ocular lesions, often the earliest detectable manifestation of sarcoidosis, are found in about one third of the cases. These lesions vary widely; for almost any part of the eye may be affected: conjunctivitis, scleral nodules, iritis, granular uveitis, posterior synechiae, vitreous opacities, chorioretinitis, and optic atrophy, alone or in combination, may occur in one or both eyes. Cutaneous lesions are polymorphic on observation but quite characteristic of sarcoidosis on histological examination. Small discrete nodules and larger nodules are found over the "butterfly" area of the face, nose, ears, shoulders, extensor surfaces of the extremities, and trunk. Finely granular infiltrative plaques, classically described as lupus pernio, subcutaneous lesions of the Darier-Roussy type, and erythema nodosum are other clinical variants. The atrophic scars which result from the healing process are often prominent. Nontender, relatively asymptomatic enlargement of the parotid or lacrimal glands may be present. Conduction

defects arrhythmias or congestive heart failure may be detected in myocardial damage from sarcoidosis. Physical examination of the lungs is usually characterized by a paucity of findings. Abdominal examination reveals nontender firm hepatomegaly and splenomegaly in about one fourth of sarcoidosis patients. Serous effusions and joint involvement are rare in sarcoidosis.

*Laboratory findings* are neither pathognomonic nor sufficiently constant to be of great diagnostic value. Among the hematological abnormalities leukopenia, moderate eosinophilia and slight monocytosis are not uncommon. An unexplained mild hypochromic microcytic anemia is occasionally observed. Hemolytic anemia or thrombocytopenia has been described in association with splenomegaly. The erythrocyte sedimentation rate is often elevated. Hypergammaglobulinemia occurs in about two thirds of patients with sarcoidosis and may or may not produce elevation of the total serum protein. An increase in serum alkaline phosphatase, usually not correlated with bone or hepatic disease, is frequently observed. Hypercalcemia, not necessarily associated with hyperglobulinemia or bone changes, is not uncommon and usually moderate in degree, although levels of 16.8 mg per cent have been reported. The serum phosphorus tends to remain normal.

*Roentgenograms* of the chest are an invaluable aid in the detection of sarcoidosis. Bilateral hilar lymph node enlargement is

frequently the earliest recognizable abnormality (Fig 43). Infiltration of the lung parenchyma may not be detectable in the early stages but later is seen to extend from the hila in reticulated strandlike areas. Extensive nodules of variable size may be present throughout both lung fields, sometimes simulating the more uniform pattern seen in miliary tuberculosis (Fig 44). The enlarged lymph nodes and the pulmonary infiltration may regress or both lesions may progressively increase. The parenchymal lesions seldom coalesce, although patchy apparently coalescent densities are seen in the mid lung field in advanced diffuse pulmonary infiltration. Severe pulmonary fibrosis with emphysematous bullae may be the only remaining findings in the advanced stage of the disease (Fig 45). Although not diagnostic, some roentgenographic lesions of sarcoidosis are highly suggestive, such as enlargement of bilateral hilar and intrapulmonic nodes in the absence of anterior mediastinal nodes.

Localization in bone as determined radiographically is seen in less than 10 to 15 per cent of patients with sarcoidosis. The middle and distal phalanges are the most common sites and the proximal phalanges, metacarpals, metatarsals and others are occasionally involved. The circumscribed bone lesions leave a punched-out appearance without reactive changes. Multiple diffuse areas of rarefaction with a reticular or lace-like pattern may be present.

FIG 44 Diffuse bilateral pulmonary infiltration simulating miliary tuberculosis in an asymptomatic patient: rapid clearing without therapy. (Courtesy Dr. H. S. Weens.)

FIG 45 Advanced pulmonary fibrosis with little evidence remaining of the initial lesions of sarcoidosis (Courtesy Dr H B Weens)

Relative *tuberculin anergy* is a nonspecific characteristic of sarcoidosis as the defect apparently applies to other antigens which produce reactions of the delayed hypersensitivity type. Approximately two thirds of patients with sarcoidosis have negative reactions to second strength tuberculin (0.005 mg of PPD or 1.0 mg of OT). The patients with sarcoidosis who do have a positive tuberculin test react least often to first strength tuberculin (0.00002 mg of PPD or 0.01 mg of OT).

The *Kveim* reaction is performed by the intracutaneous injection of an antigen prepared as a 10 per cent saline suspension from lymph nodes of patients with sarcoidosis. After a latent period of several weeks rarely as long as a year a small papule develops which histologically is indistinguishable from cutaneous sarcoidosis. The occurrence of the papule and preferably the histological demonstration of non-necrotic epithelioid cell granulomata constitute a positive test. Widespread adoption of the *Kveim* reaction has been hindered by the lack of a standardized antigen, the frequent delay in evolution of the papule, occasional severe local reactions and the slow resolution of the papule. Nevertheless the *Kveim* reaction is a valuable aid in confirming the diagnosis of sarcoidosis as false positive reactions occur in less than 6 per cent under proper conditions. During the less active stages of sarcoidosis false negative tests may occur. The lack of absolute spe-

cificity of the reaction is suggested by the production of a similar reaction in sarcoidosis with a number of antigens obtained from sources apparently unrelated to sarcoidosis.

**Diagnosis.** Correlation of clinical findings and pathological changes is often necessary before the diagnosis of sarcoidosis can be made with confidence. Sarcoidosis may be diagnosed without difficulty however in the patient with an insidious onset of mild symptoms characteristic organ involvement hyperglobulinemia negative tuberculin test compatible roentgenographic changes in the lungs or bones and biopsy confirmation of non-necrotic epithelioid cell granulomata in the tissues. Some features of the organ involvement strongly suggest the diagnosis even as isolated findings. Among these are (1) the presence of symmetrical purplish indolent nonulcerative skin lesions or the classic lupus pernio with infiltrative plaques over the nose, face, eyelids and ears, etc. (2) the unexplained occurrence of uveitis or iritis with or without asymptomatic swelling of the lacrimal and salivary glands or transient cranial nerve paralysis. (3) bilateral massive mediastinal or paratracheal node involvement in an apparently healthy patient and (4) nephrocalcinosis with hypercalcemia and a normal serum phosphorus. Difficulty in differential diagnosis usually arises when inaccessible lesions of the internal viscera occur as the only expression of the disease.

The exclusion of berylliosis, Hodgkin's disease, the lymphomas, tuberculosis and known causes of systemic granulomatous disease should be routine in the diagnosis of sarcoidosis. Some characteristics of sarcoidosis are particularly helpful in this regard. Lacrimal and salivary lesions not uncommon in sarcoidosis are very rare in tuberculosis, berylliosis or histoplasmosis. Lesions attributable to berylliosis have not been recognized in the eye. Involvement of the heart, skin or bones by lesions similar to those frequently seen in sarcoidosis is now quite rare in tuberculosis. In contrast tuberculosis not infrequently involves the pleura, peritoneum, pericardium and adrenal glands, sites which are rarely involved in sarcoidosis. The hyperglobulinemia of tuberculosis is most often characterized by a rise in alpha 2 globulin, whereas gamma globulin elevation is present in sarcoidosis. The insidious onset, mild symptoms, infrequent occurrence of fever and common occurrence of spontaneous recovery contrast sharply with the expected course of Hodgkin's disease, the lymphomas and to

a much lesser extent tuberculosis

Enlarged lymph nodes or cutaneous lesions may not be available for confirmation of the diagnosis by biopsy but the small lymph nodes in a scalenus anticus fat pad biopsy frequently contain the characteristic lesions. Pulmonary biopsy is rarely necessary although it is quite reliable. The large number of conditions which produce non-specific granulomas of the liver lessen the value of needle biopsy of the liver but this is an important diagnostic procedure. Lastly the Kveim reaction is a means of artificially inducing the characteristic histopathological changes in patients with sarcoidosis of which affords confirmation of the diagnosis.

**Course and Prognosis** The clinical course of the individual patient is unpredictable. The time of onset is infrequently established because of the insidious nature of the disease and progress is rarely reflected clinically before the occurrence of severe functional impairment. The course may be marked by remissions and exacerbations, persistence without evident change, unremitting progressive functional impairment or spontaneous recovery. In the majority of patients the disease runs its course over several years with eventual recovery. Progressive functional impairment of a particular organ unfortunately is not rare, however, unremitting disease terminating in death occurs only in a small percentage. The prognosis for all forms of sarcoidosis as a whole therefore is good.

The morbidity and mortality are largely dependent in the individual patient upon the degree of permanent functional damage to the particular organs involved. In incapacitating permanent damage most commonly follows pulmonary and ocular functional impairment. The mortality from all forms of sarcoidosis is probably less than 5 to 10 per cent. Much higher mortality rates have been observed when the functional impairment involves such vital organs as the lungs and heart. The cause of death is rarely attributable directly to sarcoidosis *per se*, the most frequent immediate cause of death is cardiac failure secondary to changes induced by sarcoidosis in the lungs.

Pulmonary tuberculosis once accounted for a significant percentage of the deaths in sarcoidosis. The incidence of tuberculous infection has progressively declined and tuberculosis is now considered an infrequent although serious complication.

**Treatment** Many approaches to therapy have been explored without discovery of a

specific therapy for sarcoidosis. Antimicrobial agents including isoniazid and streptomycin, nitrogen mustards, urethane, tuberculin, ultraviolet light, heavy metals and many others are without significant therapeutic effect. Roentgen therapy may be of benefit in certain superficial lesions. Calciferol and dihydrotachysterol have been extensively investigated and some encouraging results in cutaneous lesions have been observed, nevertheless, intolerance and toxicity sharply limit their usefulness. Splenectomy has been successful in correcting the thrombocytopenic purpura occasionally seen in sarcoidosis.

Recent attention has been focused almost entirely upon the use of corticotropin and cortisone. The active or proliferative stages of sarcoidosis show the most dramatic responses to corticotropin or the steroids. The apparent improvement often is not maintained upon withdrawal of medication and relapses are the rule. Favorable results have been most consistently achieved in ocular lesions of recent onset, in particular uveitis. There is little controversy about the indications for steroids to suppress lesions in vital tissues such as the central nervous system, heart and kidney, although the experience though encouraging is not yet sufficient to evaluate effectiveness. The use of corticotropin or cortisone is controversial, however, in asymptomatic cutaneous, lymphatic and osseous involvement, the disadvantages of such therapy apparently outweigh its advantages in the majority of cases. Acute manifestations such as diffuse pulmonary involvement with major difficulty in gas exchange have been temporarily suppressed in some instances by cortisone. It is interesting that the evidence of functional change often does not correlate with the degree of subjective or roentgenographic improvement.

It should be emphasized that the apparent beneficial effects induced by corticotropin, cortisone or more recently prednisone and prednisolone have not been shown to alter the ultimate prognosis or mortality of the disease in the majority of patients with sarcoidosis. The hazards of such therapy are certainly no less in sarcoidosis especially since the usual duration of therapy is from two to six months or it may be prolonged indefinitely. The possibility of fulfilling tuberculosis complicating adrenocorticosteroid therapy should be constantly in mind although the frequency of its occurrence has been relatively insignificant.

## Miliary Fever

**Definition** Miliary fever is an acute infectious disease which occurs in epidemic form and is characterized by abrupt onset of fever excessive sweating prostration and erythematous rash

**Incidence** Most of the epidemics have occurred in Europe and the sweating sickness which swept over England during the fifteenth and sixteenth centuries was probably miliary fever. An epidemic occurred in France in 1907. Zeiss made an epidemiological study of the disease in Russia in 1932. So far as is known the disease has never occurred in the United States.

**Etiology** The cause of miliary fever is not known nor is its mode of transmission understood. The epidemics which have been studied have occurred most frequently in the spring and summer months. Persons of all ages are susceptible. The mode of spread is rapid in this respect resembling that of epidemic influenza.

**Symptoms** The most striking feature of miliary fever is the profuse perspiration. It begins with the onset of fever which continues throughout the course of the disease. The eruption which appears on the third or fourth day is usually of the papulovesicular type occurring first on the neck back and chest and later in the axillae and between the thighs. Occasionally a purpuric form of the disease with other manifestations of hemorrhage is noted. As the rash appears there is gradual diminution in the intensity of the symptoms and after two or three days desquamation occurs. Convalescence is characterized by weakness loss of weight and slow recovery.

## Ainhum

(*Dactylolysis Spontanea*)

**Definition** Ainhum is a chronic disease of unknown cause usually affecting the little toe and characterized by the formation of a furrow at the digitoplantar fold which deepens and extends until the toe is encircled and eventually separated from the foot.

**Incidence** Ainhum has been observed chiefly on the west coast of Africa and in Brazil. Cases have been reported also from the West Indies Panama and rarely from the southern part of the United States. Apparently white people are not susceptible nearly all the cases reported have been observed among nonwhites. There is some evidence that ainhum is a familial disease since it may occur in several members of the same family or in repeated generations of the same family. It occurs chiefly in male adults between twenty five and thirty years of age.

**Etiology** There have been various theories as to etiology. Some have claimed that ainhum was related to leprosy. This seems however most unlikely it is much more probable that the disease is a trophoneurosis secondary to some local trauma. Chancey and Gipson look upon ainhum as a symptom not a primary disease and believe that it may occur in many conditions. Kean and Tucker reviewed 45 cases from the Isthmus of Panama in 1946 and concluded that the cause of ainhum is still unknown and its pathogenesis not clear.

**Morbid Anatomy** In a typical case a fibrous cord replaces the bony structures

normally attaching the bone to the foot. The skin becomes thickened and the walls of the blood vessels show an endarteritis with a secondary rarefying osteitis.

**Symptoms** According to Still the little toe is the one affected in 90 per cent of the cases more rarely the fourth toe and very rarely both the fourth and the little toe are involved. Both little toes may be attacked at the same time but the condition usually starts in one toe. The initial appearance is featured by a crack in the digitoplantar fold of the little toe. This extends laterally and finally appears on the dorsum of the toe. The distal portion of the toe enlarges and becomes bulbous. In the final stages the connection between the foot and the little toe is a slender fibrous cord which permits the toe to wobble in various directions and to interfere greatly with walking.

The course of the disease extends over several years if the toe does not undergo spontaneous amputation as a result of injury to the pedicle. The disease is practically painless.

**Treatment** Antrum is best treated in the early stages by longitudinal incision into the grooved furrow. In the later stages amputation is usually necessary.

## Milk Sickness

### (Trembles)

Milk sickness better known as the trembles is an afebrile disease due to the ingestion of milk milk products or the flesh of animals suffering from the disease.

Milk sickness is now more or less a medical curiosity but in the first half of the nineteenth century it constituted a major problem on the western frontier of the United States.

**History** Nicolay and Hay in their "History of Abraham Lincoln" claim that Nancy Hanks the mother of Lincoln died of milk sickness. In the autumn of 1818 the little community of Pigeon Creek was almost exterminated by a frightful pestilence called the milk sickness. Nancy Hanks was one of the victims.

**Incidence** At the present time milk sickness is a rare disease but a century ago the condition was common in various parts of the United States. It was quite prevalent throughout the Mississippi Valley particularly in Ohio Indiana Illinois and Michigan. There is no record of milk sickness ever having occurred outside the United States.

**Etiology** The evidence seems to be fairly conclusive that milk sickness is caused in the majority of cases by a plant known as white snakeroot *Eupatorium urticaefolium*. In New Mexico and Arizona this plant has not been observed but what is apparently the same disease also occurs in these states and is due to another herb the rayless goldenrod *Aplopappus heterophyllus* which probably contains the same toxic agent found in white snakeroot. In man the disease results from eating butter or drinking the milk from cattle which have ingested the weed. It is also possible for the human being to be poisoned by the beef of cattle that have eaten of this plant. When extract of white snakeroot is fed to laboratory animals they become ill refuse food and develop a generalized tremor. Couch who was one of the first to isolate a toxin from white snakeroot named it *trematol* which according to Couch exists in the plant partly in ester combination with a resinous acid.

**Symptoms** Milk sickness is characterized by a gradual onset of weakness loss of appetite and vomiting. These early symptoms are followed by constipation and abdominal distress. There is no fever but marked thirst is usually noted. The mind is clear but in fatal cases coma may precede death by several hours. The average duration of the disease is seven to nine days although symptoms may continue much longer.

**Prognosis** The prognosis is grave in both acute and subacute cases. Moseley states that the death rate is about 25 per cent.

**Treatment** The treatment is purely symptomatic. Prophylaxis consists of avoiding meat and milk products of animals with trembles and in pasturing cattle on cleared or plowed land.

# Diseases of Allergy

## Introduction

### RELATION OF ANTIGEN ANTIBODY REACTIONS TO ALLERGIC DISEASES

The clinical manifestations of allergic reactions result from the combination of an antigen with an antibody which has been formed by the host generally in response to prior contact with the antigen. Hay fever, asthma, food and drug allergy and allergic dermatitis usually are caused by noninfectious antigens of environmental or extrinsic origin. However, the pathological changes of chronic infection often may be caused in large part by an allergic response of the host to the invading microorganism. Furthermore, the morphological and physiological changes which characterize such diseases as periarthritis nodosa, lupus erythematosus, rheumatoid arthritis, glomerulonephritis, rheumatic fever and encephalomyelitis are thought by some to result from autoantibody production to antigens present in the individual's own tissues. In chronic thyroiditis (Hashimoto's disease) precipitating antibodies to human thyroglobulin have been found, and an analogous pathological process has been produced by injecting rabbit thyroid into rabbits. In erythroblastosis fetalis, antibodies derived from the mother pass through the placenta to combine with antigens on the erythrocytes of the fetus. The degeneration of homologous skin and other tissue grafts may be also attributed to the formation by the recipient of antibodies to the grafted tissues. Recent studies with inbred strains of mice have shown that injection of spleen cells or whole blood into fetuses *in utero* endows them with the ability to tolerate skin grafts from donor strains which would ordinarily be rejected; this has been termed *actively acquired tolerance* (Medawar).

Destruction of the graft could be effected by transplantation of a lymph node from an animal which had previously rejected a graft. From the immunological standpoint, therefore, allergy is an ever broadening field with a profoundly important relation to pathology and clinical medicine.

Allergic reactions to extrinsic antigens may be separated broadly into two groups. One of these is associated with the presence of circulating antibody in the serum of affected individuals and includes anaphylaxis, Arthus reactions, serum sickness, allergies involving the characteristic wheal and erythema reaction, hay fever, urticaria, angioedema, asthma, and certain gastrointestinal allergies. In the other, an antibody having a high affinity for tissue cells has been demonstrated and circulating antibody is thought not to be involved. This latter group includes contact dermatitis (e.g., poison ivy sensitivity), drug allergies (sulfonamides, penicillin), and certain allergies of infection. The allergic reactions observed in these two groups are frequently referred to as immediate and delayed, respectively. These terms are sometimes useful in distinguishing anaphylaxis and urticarial reactions from contact dermatitis and tuberculin sensitivity, but are ambiguous as applied to the Arthus and tuberculin reactions, as well as drug sensitivities, in which microscopic evidence of reaction occurs early but in which several hours are required before they become visible grossly.

Since allergic diseases are a manifestation of the response of tissues to an antigen-antibody reaction, an understanding of their mechanism depends largely upon a knowledge of the seven aspects to be considered in detail subsequently. None of these problems have been completely solved, but a substantial body of information has

been accumulated from studies on human allergy and from animal experimentation

**1 The Nature of the Inciting Antigen(s)** Proteins and polysaccharides are capable of stimulating antibody formation in animals and in man and these comprise most of the allergenic substances. Both are widely distributed throughout the animal and plant world and almost any protein constituent (and some polypeptides) can under suitable experimental circumstances be shown to elicit an antibody response. In sensitivities caused by low molecular weight substances such as common drugs it is generally believed from the work of Landsteiner and co workers that these substances are in some way coupled to protein in the animal and in this way induce the formation of antibody. Sensitization is more easily accomplished in animals and man with low molecular weight substances which combine readily with protein than with less highly reactive substances. To be antigenic proteins must be foreign to the circulation of the host *e.g.* antibodies are not produced by the injection of human serum proteins from man to man. In hemolytic anemias the production of auto antibodies to erythrocyte antigens may occur but the mechanism of this sensitization is unknown. A recent case was shown to be due to production of antibodies to one of the rare Rh factors *e* or *Hr* by a person whose erythrocytes contained this antigen.

Purified polysaccharides are antigenic in certain species but not in others. The type specific pneumococcal polysaccharides and dextrans for example are antigenic in man and give rise on injection to precipitins and to wheal and erythema sensitivity. Antibodies and skin sensitivity to certain polysaccharides occur in a considerable proportion of humans sensitization probably resulting from microorganisms in the nasopharynx and the gastrointestinal tract which produce these polysaccharides. In deed the infusion of certain dextrans into such sensitized persons has produced urticarial and other anaphylactic symptoms. In other species such as the rabbit and guinea pig these polysaccharides are antigenic only when combined with protein or in the intact microorganism. High molecular weight preparations of the completely synthetic polyvinylpyrrolidone have been shown to be antigenic in humans. Gelatin long thought not to be an antigen has also been shown by Maurer to be antigenic in several species.

In experimental animals using well de-

fined or purified proteins the sensitivities produced are most frequently associated with circulating antibody and are similar to the allergies encountered in the administration of foreign proteins (*e.g.* horse antitoxins) to man as typified by serum sickness and anaphylactic reactions. The high proportion of allergic sensitizations affected by contact with such foreign proteins in man necessitates the use of a preliminary intracutaneous test prior to parenteral administration of even small amounts of an antitoxin or other foreign protein. This may be performed with about 0.01 to 0.02 ml of 1:10 diluted serum. A positive wheal and erythema reaction after about 20 minutes indicates sensitivity.

Delayed type allergic reactions are less amenable to study since they are generally the result of infections with intact microorganisms which are extremely complex mixtures of antigens (*e.g.* tuberculin mal-*le*in) and thus are far more complicated from the immunological standpoint. Drug sensitivities and poison ivy sensitivity are also of this delayed type. The experimental production of drug sensitivities in animals provides instances of less complicated antigenic systems.

The factors determining whether a substance will be antigenic and whether allergic sensitization will or will not be associated with circulating antibody are completely obscure and our present knowledge is entirely empiric.

**2 Ways in Which Sensitization Can Take Place** Sensitization to various antigens may occur following introduction of antigen by parenteral respiratory oral or other routes. In experimental animals and man sensitization to serum proteins of another species can be induced in almost all instances. Serum sickness has occurred in over 90 per cent of persons treated with large amounts of horse antipneumococcal serum. Similarly the development of skin sensitivity to tuberculin may be produced in tuberculin negative persons by vaccination with BCG. On the other hand only a relatively small proportion of the population develop the usual allergic diseases produced by grass and tree pollens, danders and certain foods. Efforts to induce skin sensitivity hay fever asthma or other manifestations of allergy with these antigens in man have been generally unsuccessful although anaphylactic sensitivity may be produced in guinea pigs fairly readily. Naturally occurring human allergies are sometimes termed spontaneous allergies to distinguish them from induced allergies.

### 3 Predisposing or Hereditary Factors

Studies in various experimental animals have shown that by inbreeding and selection it is possible to establish strains differing widely in susceptibility to certain bacterial infections capacity to produce antibody and ability to become sensitized to certain simple chemical compounds. Such data indicate that heredity influences these phenomena. Evidence that similar genetic factors affect the development of the spontaneously occurring allergies in man is far more difficult to obtain. Suggestions that these allergies are inherited on a Mendelian basis have been based on the occurrence of families with a large proportion of allergic members. Critical re-examination of such family studies established that in about 40 per cent of the families only a single individual was allergic and that in an additional 25 per cent only one other member had allergy, only a small fraction of the families had many allergic members. With only such data the existence of genetic determinants in these human allergies must be considered as unproved.

### 4 Properties of the Antibodies Involved

A number of antibodies have been recognized in both experimental animals and man which differ in their capacities to induce allergic sensitivities. These antibodies may vary in their ability to react with antigen to sensitize a heterologous species passively to elicit a wheal and erythema reaction or in their affinity for tissue cells. To a limited extent certain of these properties have been related to certain types of allergic response.

The usual type of precipitin produced after the injection into a rabbit of a foreign protein such as egg albumin can passively sensitize the guinea pig or rabbit for anaphylactic shock or the Arthus reaction. However the antibodies produced by the rabbit to such an antigen are not all identical but are thought to represent a spectrum of antibodies differing in reactivity. Certain of the antibody molecules in such an antiserum do not by themselves precipitate with antigen. They precipitate with other antibody molecules if sufficient antigen is added at one time but remain in the supernatant serum if precipitation is carried out fractionally by successive serial addition of small amounts of antigen. This type of antibody is termed nonprecipitable since it cannot precipitate with antigen by itself but can only attach itself to a specific precipitate formed in the presence of precipitable antibody. Precipitable and nonprecipitable rabbit antibodies to egg albumin

have been shown to be equally effective in inducing passive anaphylactic sensitization in the guinea pig; the nonprecipitable antibody however was incapable of inducing an Arthus type of sensitization passively. Conversely certain types of horse antibody such as horse antibody to the pneumococcal polysaccharides are for unknown reasons incapable of inducing passive anaphylactic sensitization of the guinea pig. However they precipitate with the pneumococcal polysaccharides and have been shown to induce a passive Arthus reaction in the guinea pig. From this and other evidence the Arthus reaction may best be interpreted as due to mechanical damage to blood vessels resulting from precipitation of antigen and antibody while anaphylaxis is a consequence of the combination of antigen with antibody and is largely independent of precipitation. Some individuals have been shown to produce a nonprecipitating variety of diphtheria antitoxin which was also capable of passive anaphylactic sensitization of the guinea pig. Precipitating antibodies have been found in humans who have developed serum sickness. Since horse serum is a complex mixture of antigens the relation of the clinical manifestations to the disappearance of antigen and the appearance of antibody is difficult to determine. However in studying serum sickness following the administration of crystalline bovine albumin, Kendall was able to demonstrate that the clinical manifestations coincided with accelerated disappearance of antigen from the circulation and that circulating antibody appeared shortly after symptoms subsided.

It is of importance to remember that persons who have experienced serum sickness or formed antibody to such foreign protein may be thrown into anaphylactic shock. Furthermore lesions wholly similar to those of periarteritis nodosa have been found in animals and in man following administration of large amounts of foreign serum. Rare instances have also been recorded in which an acute demyelinating disseminated encephalomyelitis followed the administration of pertussis vaccine.

The spontaneous allergies of the wheal and erythema type have been shown frequently to be associated with antibody in the circulating blood. The antigen or antigens responsible for such sensitivity may be identified by skin testing with a variety of extracts from trees, grasses and pollens. Because of the danger of inducing severe systemic reactions minute doses of such

extracts are employed. Extracts are standardized on the basis of their protein nitrogen content and their potency is frequently expressed in units; one unit is 0.01 microgram protein nitrogen. Two techniques are generally used—the scratch test and the intracutaneous test. The former is considered to be somewhat safer but the latter is more sensitive. Skin tests are generally performed on the arm or forearm, a location which offers the opportunity for controlling development of any systemic reaction from the test by application of a tourniquet. The scratch test is usually performed by making a small scratch with a hypodermic needle, gently rubbing a drop of the allergenic substance into the skin over the scratch. The intracutaneous test is carried out by the injection into the most superficial layers of the skin of about 0.01 ml of the allergen solution; this quantity is usually the minimal amount producing a detectable bleb. Control tests with diluent alone are always carried out. The appearance after fifteen to thirty minutes of a wheal with surrounding erythema which is absent in the control is taken as a positive test. In carrying out such tests it is essential to start with extremely dilute solutions (10 to 100 units per ml) to avoid severe constitutional reactions. If negative results are obtained, further tests may be made with increasing concentrations usually tenfold increments.

Antibodies in the serum of persons showing such skin sensitivity may be identified by passive transfer of such serum into the skin of nonsensitive persons (Prausnitz-Kustner reaction). After six hours to five or ten or even more days, antigen is injected into the same site and the occurrence of a wheal and erythema reaction are noted.

While allergic persons generally show skin sensitivity of the wheal and erythema type to one or more of the offending antigens, it is not uncommon to find skin sensitivity in those who do not show clinical manifestations of disease on exposure to this allergen. A substantial proportion of persons with skin sensitivity to a given antigen have antibodies in their serum capable of giving a Prausnitz-Kustner reaction. Despite extensive study, no unequivocal *in vitro* manifestation of the presence of these skin sensitizing antibodies has been demonstrated. Recent attempts to associate them with a nonprecipitating antibody are open to considerable question in view of the failure to employ

serum shown to be free from precipitating antibodies to other antigenic impurities.

Another type of antibody in human serum to antigens associated with the wheal and erythema types of allergy has been demonstrated by Cooke and co-workers by Harley and subsequently by others. This antibody is formed in response to the parenteral injection of antigen. It may be formed in sensitive individuals receiving injections of antigens such as ragweed extracts for therapeutic purposes and is also formed when nonallergic individuals receive similar injections. These antibodies do not sensitize human skin but combine with their homologous antigen so that the antigen cannot react with the skin sensitizing antibody to give a wheal and erythema response. These antibodies, which have been termed *blocking antibodies*, differ in several respects from skin sensitizing antibodies. They are stable to heating at 56° C for four hours, a procedure which destroys the activity of the skin sensitizing antibody. Unlike the skin sensitizing antibody, they diffuse away from the site of injection and also are able to pass the placenta. Finally, recent studies have shown that sera with high titers of blocking antibody to ragweed extract not only combine with antigen to prevent a skin reaction but can also bind antigen so that the antigen is unable to combine and fix complement with rabbit antibody to ragweed extracts; this latter capacity is measured by a complement fixation inhibition or indirect complement fixation test. The blocking antibody will also agglutinate tannic acid-treated erythrocytes coated with antigen and can inhibit precipitation of rabbit antiragweed serum by ragweed extracts. Blocking antibody may eventually be shown to be a classic type of precipitating antibody if obtainable in adequate quantities. The major unsolved problems in wheal and erythema allergy are the nature of the skin sensitizing antibody, the manner in which it is produced, how it is able to attach itself to skin and whether or not it would behave as a precipitating antibody if obtained in sufficient quantities.

The antibody associated with allergies of the delayed type appears to be different from these other antibodies. People and animals showing delayed or tuberculin type sensitivities do not appear to have antibodies which can passively transfer this type of sensitivity in their serum. Studies of Landsteiner and Chase, however, have shown that skin sensitivity of the delayed

type in guinea pigs may be transferred passively to nonsensitive animals of the same species by the administration of cell exudates. With larger amounts of washed cell exudates Chase has also been able to transfer anaphylactic sensitivity and anti-toxic immunity. Studies in man have also successfully demonstrated passive transfer of sensitivity to tuberculin by injecting leukocytes from tuberculin positive into tuberculin negative subjects. Lysed cells have been found to be capable of effecting this transfer. The sensitivity does not make its appearance for two to three days after the cells are introduced. The mechanism of transfer of delayed sensitivity has not yet been clearly defined.

**5 Quantitative Relationships between Antibody and Antigen and the Allergic Responses** An important consideration in the understanding of the mechanisms of allergy is a knowledge of the amounts of antibody required to bring about allergic reactions. Passive sensitization may be effected by injecting measured volumes of rabbit or guinea pig antiserum to purified antigens of known antibody content into guinea pigs and then after a suitable interval injecting antigen. With this technique it has been shown that only 30 micrograms of rabbit or guinea pig antibody nitrogen need be present in a 250 gm guinea pig for uniformly fatal anaphylactic shock to occur with human diphtheria antitoxin about 100 micrograms was needed. Uterine strips from a guinea pig passively sensitized to egg albumin might be expected to contain about 0.01 microgram of antibody N. Such uterine strips show maximal contraction when exposed to antigen in a Dale bath. Ovary has shown that injection into guinea pig skin of but 0.003 microgram of antibody N was sufficient to cause a wheal and erythema type of reaction on contact with antigen. This reaction called passive cutaneous anaphylaxis is readily demonstrated by intravenous injection of antigen mixed with a dye such as Evans blue. The skin sites at which the antibody was placed become blue owing to increased permeability into the wheal. The latent period in passive anaphylaxis is the time interval between the sensitizing dose of antibody and the shocking dose of antigen has been shown both in systemic anaphylaxis and with isolated uterine strips to be a function of the quantity of antibody used for sensitization. With large amounts of antibody N fatal anaphylaxis could be obtained with no latent period but as the quantity of antibody N used for sensitization decreased the

latent period increased. Passive cutaneous anaphylaxis in guinea pigs can be produced only with serum from humans with induced allergies and not from those with spontaneous allergies.

The passive Arthus reaction requires far larger quantities of antibody N. To produce a minimal Arthus reaction 25 micrograms of antibody N in the rabbit and about 10 micrograms in the guinea pig must be injected into a skin site. These quantities of antibody are of the order of 1000 to 2500 times larger than that estimated to be present in a contracting uterine strip or 3000 to 10 000 times greater than that responsible for passive cutaneous anaphylaxis in guinea pig skin.

The very minute amounts of antibody required to elicit wheal and erythema and anaphylactic reactions suggest the possibility that the failure to detect *in vitro* manifestations of skin sensitizing and blocking antibodies may be due to the small quantities involved. It cannot be excluded however that certain of these antibodies may possibly prove to be of the nonprecipitable variety which as described above can produce anaphylactic sensitivity.

**6 The Mechanisms by Which Combination of Antigen and Antibody Causes an Allergic Response** A number of the physiological and pathological manifestations of immediate type anaphylactic reactions notably the patterns in anaphylactic shock the wheal and erythema reaction in human skin and the contraction of smooth muscle may be produced by the injection of histamine and these findings have led to the belief that the antigen antibody combination liberates histamine. Further evidence rests on the similarity of the effects produced in various species by certain diamines and mono- or diamidines a group of substances termed histamine liberators. For instance if a sensitized guinea pig which has also received an injection of pontamine sky blue is thrown into anaphylactic shock the localization of the blue dye in certain characteristic areas is very similar to that produced in a guinea pig injected with a histamine liberator. Furthermore the areas of skin selectively colored by the blue dye in both instances are those which contain the highest concentrations of histamine.

Anaphylactic shock and the effects of histamine itself or of histamine liberators in the guinea pig may be prevented by the antihistamine drugs.

However other species notably the mouse are extraordinarily refractory to

histamine and in these species 5 hydroxy tryptamine (serotonin) may play the dominant role in anaphylaxis lysergic acid diethylamide and reserpine inhibit anaphylactic contraction in the sensitized mouse uterus while antihistaminics are ineffective Humans with malignant carcinoid show a peculiar type of bronchial asthma and patchy flushing of the skin similar effects can be produced with 5 hydroxytryptamine Carcinoid tissue contains much 5 hydroxytryptamine and these patients have high blood serotonin

Evidence for yet another substance slow reacting substance (SRS) has been obtained with sensitized guinea pig and human asthmatic lung tissue When the effects of histamine are counteracted by the antihistamines a substance is released on contact with antigen which causes a slow sustained contraction of guinea pig ileum it is distinct from other substances known to affect smooth muscle

Little is known of the mechanisms by which antigen antibody combination brings about other allergic manifestations

**7 Factors Affecting Antibody Formation and the Allergic Response** Roentgen irradiation has been shown to reduce or inhibit antibody formation if administered prior to the injection of antigen Several substances notably the nitrogen mustards corticotropin and cortisone have also been shown to suppress but not completely abolish antibody formation and to have a suppressive effect on the specific anamnestic response As a consequence in actively sensitized animals receiving these drugs the Arthus reaction which requires fairly substantial antibody levels has been reduced in severity However anaphylactic reactions in actively sensitized animals which require relatively minute quantities of antibody are not affected by these substances Cortisone and corticotropin have been shown not to influence the combination of preformed antigen and antibody in that both passive anaphylaxis and the passive Arthus reaction are unaffected Cortisone has been found useful in the treatment of certain allergies notably serum sickness hay fever asthma contact dermatitis infantile eczema and drug allergies and less effective in urticarias and angioedema in large doses it also reduces the intensity of the tuberculin reaction These actions may also result from an effect on inflammation rather than from suppression of antibody formation since the cortisone frequently acts much more

rapidly than inhibition of antibody synthesis would be expected

## Hay Fever

**Definition** Allergic rhinitis is a reaction of the nasal mucosa manifested by edema itching and increased mucous secretion and is the result of allergy to a specific antigen When caused by allergy to pollens it is called hay fever or pollenosis and is characterized by seasonal recurrence during the period of pollination of the causative plants Allergic rhinitis due to antigens other than pollens is called nonseasonal or perennial allergic rhinitis The term vasomotor rhinitis is applied both to perennial allergic rhinitis and to morphologically similar chronic edema of the nasal mucosa due to nonantigenic irritants or probably in some cases to neurogenic and psychosomatic causes

**Etiology** The occurrence of symptoms of hay fever depends upon the development of allergy of the wheal and erythema type for pollen and subsequent inhalation of the specific pollen in adequate quantity to elicit the allergic reaction The allergic sensitization producing hay fever is the

same type associated with infantile eczema atopic dermatitis bronchial asthma and certain forms of food allergy so that persons manifesting one of these diseases frequently develop others of the group. While diseases of this group tend to occur in certain families neither the particular disease manifestation nor allergy to a specific antigen is inherited only a tendency to become allergic to antigens to which the individual is exposed.

In general only those plants depending on the wind for cross pollination and producing an abundance of buoyant wind borne pollen are important factors in the causation of hay fever. These include grasses many families of weeds and most of the trees of temperate climates. Plants with showy and odoriferous blossoms including roses and goldenrod which are adapted to insect pollination and produce relatively small amounts of heavy sticky pollen rarely cause hay fever. Allergy to tree and weed pollens is specific for the genus rather than the species of plant so that the use of pollen of one species of a genus in testing and treatment suffices. In the case of the grasses the pollens of all the common genera are antigenically quite similar so that for practical purposes a mixture of the pollens of three or four of the grasses most common in a given area may be used as if a single antigen.

Specific diagnosis of hay fever requires a knowledge of the flora of the patient's locality and the seasons of pollination of the plants. Throughout the greater portion of the United States and southern Canada spring hay fever (April and May) is due to tree pollens early summer hay fever (June and July) to grass pollens with plantain and sorrel also important in some areas and late hay fever (August and September) to weed pollens. The important trees vary considerably in different areas ash beech birch cedar hickory maple oak sycamore and poplar produce an abundance of antigenic windborne pollen and may be presumed important where they grow commonly. The pollens of the pines and other conifers are relatively less antigenic and less often cause hay fever even where abundant. The grass pollens are everywhere important their season being prolonged through much of the year in the extreme south. In the East and Middle West ragweed is by far the most important weed pollen it also occurs in most of the Far West except for the North Pacific coast but its importance in the mountain and coast areas is less than that of sage

amaranth and Russian thistle. For detailed accounts of the windborne pollens causing hay fever in various areas of the United States and southern Canada reference to the works of Wodehouse and of Durham is suggested. The tree and grass hay fever seasons in northern Europe correspond closely to those of the United States the weed pollens are relatively much less important ragweed not being indigenous to the area.

**Incidence.** It has been estimated that 8 to 10 per cent of the population of the United States is affected by hay fever but a large proportion of these cases are not severe enough to require medical treatment. The white Negro and yellow races are susceptible. Both sexes are equally affected. In areas where ragweed is abundant approximately 75 per cent of hay fever sufferers are affected by this pollen in 50 per cent it is the only significant cause. About 50 per cent are affected by grass pollens alone or in combination with other pollens. Tree hay fever is less common and usually occurs in patients also affected by grass or weed pollens.

**Pathology and Physiology.** Since one of the chief functions of the nose is to warm and purify the inhaled air a large proportion of suspended dust particles are deposited on its mucosa which is therefore peculiarly exposed to inhaled allergens. Sensitization of the type causing hay fever consists in the development of sensitizing antibodies present in the conjunctiva nasal mucosa skin and blood plasma. Contact of the allergenic pollen with the sensitized mucosa elicits an antigen antibody reaction which is manifested by engorgement of the blood vessels edema increased secretion of watery mucus and itching which gives rise to sneezing. The physiological effects of the antigen antibody reaction are believed to result from the release of histamine which can be demonstrated when specific antigen is added to the patient's blood *in vitro*. There is little evidence that the central nervous system is involved.

While the symptoms produced by inhalation of pollen are localized to the mucosae with which it comes in contact the sensitization is systemic. Injection of too large a quantity of antigen into a highly allergic patient in a diagnostic skin test or in treatment may elicit a constitutional reaction similar to experimental anaphylactic shock. It is manifested within twenty minutes or less by coughing sneezing asthma urticaria or general flushing and itching of

the skin and in severe cases collapse. Such reactions may be serious or even fatal if not promptly treated.

Repeated injections of the antigen for the specific treatment of hay fever stimulate the formation of blocking antibody distinct from the pre-existing sensitizing antibody. This blocking antibody appears to be responsible for the increase of tolerance for injected antigen and may be responsible for the clinical benefits of treatment although evidence of the latter is still inconclusive.

**Symptoms.** The symptoms of hay fever characteristically recur each year at the same season with the beginning of pollination of the causative plant; the date of onset in a given locality rarely varying by more than a week or so although the amount of pollen produced and hence the severity of symptoms vary considerably from year to year depending on the weather. During the season symptoms are worse on dry windy days and decrease during heavy rain. They usually tend to be worse in the morning. The termination of symptoms at the end of the pollen season is less abrupt than the onset owing to the persistence of pollen in the air and in many cases to the complicating effects of nonseasonal allergens and superimposed respiratory infections.

The most characteristic symptom is sneezing usually in paroxysms of several sneezes in rapid succession. The nasal mucosa is congested and there is an increased flow of watery mucoid secretion. The conjunctivas are red and itchy with increased lacrimation. Itching of the soft palate and pharynx is usual and in severe cases the ears may also itch severely. Cough, wheezing and dyspnea are commonly present but are actually indicative of pollen asthma rather than hay fever itself.

**Diagnosis.** When the pattern of seasonal recurrence has become established the diagnosis of hay fever is easy and the causative pollen is usually apparent to the physician acquainted with the pollen seasons of the area. During the first season differentiation from infective rhinitis may be difficult although the paroxysmal sneezing, the itching of the eyes and pharynx, the watery nasal discharge, the normal temperature, the absence of sore throat and of general malaise are helpful as is a personal or family history of allergies of the wheal and erythema type. In doubtful cases smears of the nasal secretion may be stained with Wright's stain, an abundance

of eosinophils is characteristic of allergic rhinitis.

Allergic rhinitis due to antigens other than pollens particularly airborne molds such as *Alternaria* and *Hormodendrum* and seasonal insects may have a seasonal exacerbation during warm weather but lacks the precise onset and cessation characteristic of pollen allergy. Occasional cases of allergic rhinitis due to fruits or vegetables eaten at certain seasons may be confusing but can be distinguished by skin tests.

The diagnosis of hay fever is established and the specific cause demonstrated by eliciting the wheal and erythema reaction in skin tests with the antigen performed with the technique and precautions outlined in the introductory section on allergy. Both the scratch test and the intracutaneous test are useful; the former is simpler and involves less danger of a general constitutional reaction; the latter is more sensitive and more useful in estimating the degree of sensitization. For the typical case of seasonal hay fever a few tests with pollens appropriate to the season and locality suffice. If the season is prolonged additional tests with mold spores and other inhalants may be added (See section on Nonseasonal Allergic Rhinitis).

Reactions are read after ten to fifteen minutes. A slight but definite wheal is considered one plus; moderate reaction (wheal 6 to 10 mm without pseudopods) two plus; a wheal of 10 to 15 mm (with pseudopod formation) marked or three plus; and wheals larger than 15 mm four plus.

The initial intracutaneous tests with pollens should be made with solutions of antigen containing no more than 10 protein nitrogen units per ml and not more than six tests should be done at one time. If little or no reaction is obtained subsequent tests may be made with solutions containing 100 units and then 1000 units per ml until a two or three plus reaction is elicited.

The degree of sensitivity is roughly indicated by the highest dilution producing a marked (three plus) skin reaction in the intracutaneous test. Class A: highly sensitive 10 units per ml. Class B: average 100 units and Class C: less sensitive 1000 units. A moderate (two plus) reaction to the 1000 unit strength is evidence of sensitivity if consistent with the seasonal incidence of symptoms. Many patients with definite allergy to one pollen show slight or moderate reactions to many other pollens. These indicate slight or potential

allergy but specific treatment is indicated only for those which the history shows to be important

**Prognosis** Hay fever is essentially a permanent idiosyncrasy more troublesome than disabling and without danger to life. Variations in severity may occur spontaneously or as a result of a change of residence or habits which alters the intensity of exposure to pollen. Since hay fever is a manifestation of allergy of the wheal and erythema type patients affected by it often develop other diseases of this type particularly asthma. This complication eventually occurs in approximately 30 per cent of untreated patients but the incidence is greatly reduced by specific treatment. Patients with hay fever are unusually susceptible to upper respiratory infection and the development of sinusitis is a common complication especially of the fall type which persists until the cold weather when respiratory infections are prevalent.

**Treatment** The treatment of hay fever consists of (1) avoidance of the causative pollen, (2) palliative drug therapy, (3) lessening of sensitivity by injections of the specific antigen. When treatment is started during the season of symptoms the first two methods produce the most immediate relief but the most satisfactory results over the long term are achieved by antigen injections started at least two months before the season.

**Avoidance** When the severity of symptoms warrants it relief may be obtained by a trip to an area known to be free of the causative pollen or by a sea voyage. Exposure to pollen may also be lessened by air conditioning or the use of suitable pollen filters in the window of the bedroom or other rooms to a lesser degree by simply remaining indoors with windows and doors closed.

**Palliative Treatment** The most useful drugs are the antihistaminics which produce satisfactory relief in a majority of cases. Triphenylamine (Pyribenzamine) 50 mg, chlorphenylpyridamine (Chlortrimeton) 4 mg, and chlorcyclizine (Perazil or DiParalene) 25 mg are examples of the many suitable drugs of the group. They may be taken after each meal and if necessary every four hours at night. Phenergan (12.5 to 25 mg) has a more potent and lasting antihistaminic action and is useful at bedtime but is too sedative for general use during the day.

Patients with severe symptoms or with coexisting pollen asthma not relieved by the antihistaminics may be given prednisone or

prednisolone 5 mg every six to eight hours or corticotropin gel 40 units intramuscularly daily. The dose of either drug should be reduced by 25 to 50 per cent as soon as relief is obtained and is generally continued only for seven to ten days at the height of the pollen season.

For relief of the conjunctival symptoms eye drops containing cocaine hydrochloride 0.3 per cent, epinephrine hydrochloride 0.025 per cent and boric acid 3 per cent in rose water are useful, one drop in each eye two or three times a day if necessary.

**Specific Treatment** Treatment with specific pollen antigen consists of a series of twelve to sixteen subcutaneous injections of gradually increasing doses of antigen given at intervals of three to seven days starting two or three months before the season. The following table shows approximate doses which must be modified according to the patient's reaction.

Dosage in Protein Nitrogen Units for Treatment of Hay Fever

DOSE	CLASS A (HIGHLY SENSITIVE)	CLASS B (AVERAGE CASE)	CLASS III (LESS SENSITIVE)
1	2	10	20
2	5	20	40
3	10	40	80
4	20	80	150
5	35	140	250
6	50	200	400
7	75	300	600
8	110	400	850
9	150	600	1200
10	200	800	1800
11	300	1000	2500
12	400	1500	3500
13	600	2000	5000
14	800	3000	6500
15	1000	4000	8000
16	1000	5000	10000

The injections are given on the lateral aspect of the upper arm or the thigh with a rubber tourniquet and epinephrine 1:1000 at hand for use in case of a constitutional reaction. The patient is kept under observation for twenty minutes after the injection.

Normally the injections produce a slight local swelling which subsides within twenty-four hours. If the local reaction is troublesome or lasts longer than thirty-six hours the same dose is repeated after the usual interval then increased or again repeated as indicated by the resulting reaction.

If a constitutional reaction follows the

injection a rubber tourniquet is applied promptly proximal to the site of the injection and epinephrine 1:1000 0.4 to 0.6 ml injected every ten minutes until relief is obtained. Mild constitutional reactions may be relieved by tripelennamine (Pyribenzamine) 50 to 100 mg orally or 25 mg subcutaneously but since they may rapidly become more serious the inexperienced physician is wise to use epinephrine. When a constitutional reaction has occurred the dosage should be dropped back two steps on the schedule and then increased more gradually. If a second constitutional reaction occurs at the same dosage the subsequent dosage should be kept below that level.

The dose which has been reached at the beginning of the season is repeated weekly during the period of active pollination without further increase.

Suitable injection treatment produces satisfactory results in at least 75 per cent of cases but may be supplemented with drug treatment if necessary. If the results of injection treatment are not satisfactory and no undue reactions have occurred the following season one may plan to reach a dose two or three times as great.

If treatment is to be repeated the following year more satisfactory results may be expected with no greater total number of injections by the perennial method of treatment. After the end of the season the same dose is repeated every four weeks until the following spring. When a fresh supply of extract is obtained the dose must be reduced 50 to 60 per cent to allow for the deterioration of the year old antigen. It can then be gradually increased to the previous or a somewhat higher dose by giving injections every two weeks.

If injections of antigen have not been given before onset of symptoms attempts to start specific treatment during the season are rarely effective and palliative treatment is more satisfactory.

#### NONSEASONAL ALLERGIC RHINITIS VASOMOTOR RHINITIS

Allergic rhinitis due to nonseasonal antigens is essentially similar to hay fever and often affects the same persons but if exposure to the antigen is persistent it assumes a chronic form. Perennial allergic rhinitis may be due to inhaled antigens (inhalants) or to allergic reactions to the bacteria of the nose and paranasal sinuses and rarely to foods or ingested drugs. Ordinary house dust contains antigens distinct from the known substances contribut-

ing to its formation but possibly resulting from their deterioration and is one of the most important inhalant antigens.

Vasomotor rhinitis practically indistinguishable from chronic allergic rhinitis may result from prolonged exposure to nonantigenic irritants of which the most frequently encountered are vasoconstricting nose drops such as ephedrine, Privine and Neo-Synephrine. When these drugs have been used persistently they frequently prove to be the principal cause of prolonged rhinitis and marked improvement results within a week after their discontinuation. A similar edema of the nasal mucosa can also result from psychosomatic factors which may occasionally be the sole cause but more often are a contributory cause in allergic cases.

In rhinitis due to any of these causes the nasal mucosa is markedly swollen and presents a dull red or grayish appearance. In chronic cases there are often mucous polyps particularly in the ethmoid region. The nasal secretion is increased in amount and mucoid in character with an abundance of eosinophils in the stained smear.

To evaluate the importance of extrinsic allergens skin tests with eighteen or twenty of the principal inhalants should be done as outlined in the section on asthma. Tests with food antigens are indicated only if the history is suggestive or if the inhalant tests give negative results. Skin tests are not satisfactory for determining the existence of bacterial allergy in the causation of vasomotor rhinitis. It may be suspected in the presence of associated chronic sinusitis particularly hyperplastic sinusitis and is strongly suggested by the coexistence of nasal polyps. If the patient has been using vasoconstricting nose drops persistently their use should be discontinued before the importance of other factors is estimated. The importance of psychogenic factors in certain cases of vasomotor rhinitis either as the principal cause or as a contributory factor in allergic patients must be judged by the history by the careful elimination of allergic and ineffective causes and by observation over a period of time.

Treatment is best directed to the cause. In cases due to specific inhalant antigens such as feathers or animal danders elimination of contact is far more effective than injection treatment. Allergy to inhalants with which contact is unavoidable such as house dust and airborne mold spores is treated by injection of antigens in progressive dosage similar to that advised for

pollen antigens For symptomatic treatment the antihistaminic drugs in the doses advised for hay fever are useful but are somewhat less effective in chronic than in acute cases Prednisone prednisolone and corticotropin are highly effective in severe cases but the relief is only temporary and prolonged use involves risk of undesirable side effects

Perennial allergic rhinitis like hay fever is not dangerous to life but if specific treatment is neglected is often followed by asthma Susceptibility to nasal and sinus infection is also greatly increased

## Asthma

**Definition** Bronchial asthma is a type of pulmonary incompetency due to constriction of the bronchi and edema of the bronchial mucosa which are caused by the response of an allergically susceptible bronchial tree to specific allergic and/or nonspecific irritative stimuli Typically it occurs in paroxysmal recurrences with intervals of relative comfort but may also assume a mild continuous form with exacerbations or the acute attack may persist for days or weeks as *status asthmaticus*

**Etiology** Approximately half of the cases of bronchial asthma result from allergy to external antigens most often dusts suspended in the inhaled air but occasionally ingested foods or drugs This type of asthma is usually classed as *extrinsic asthma* The remainder in which no evidence of hypersensitivity to specific allergens is found by skin tests is classed as *intrinsic asthma* Most of the cases in the latter category can be shown to result from infections of the respiratory system

Asthma of the extrinsic type results from the same wheal and erythema type of hypersensitivity as hay fever differing only in the site of the allergic reaction and the two conditions frequently coexist in the same person The reasons for localization

of the allergic reaction in the bronchi rather than the nasal mucosa are not established although it has been suggested that inflammation of the bronchial mucosa by intercurrent infections such as acute bronchitis or pertussis or by nonspecific chemical irritants may play a part in some cases

The allergens causing extrinsic asthma are the same as those causing allergic rhinitis By far the most important are inhaled organic dusts such as pollens mold spores animal danders feathers insecticides glue and lint from fabrics Ordinary house dust contains in addition to the substances obviously contributing to its formation other antigens apparently arising from the disintegration of fibers or from contamination with molds and bacteria Although house dust is a complex and variable mixture for most practical purposes an extract of a mixture of dusts from several houses may be used as if it were a single antigen Grain dust flour spices and such vegetable seeds as cottonseed flax seed and castor bean are important causes in persons exposed as a result of their occupations and occasionally affect those with only casual contact The proportion of cases due to foods is not large but practically any food may occasionally be a cause Among those most active as antigens are eggs fish shellfish nuts spices and chocolate In general the antigens are proteins or similar compounds of some what lower molecular weight but certain synthetic drugs such as aspirin may cause severe asthma presumably through acting as haptens

The infections of the respiratory system causing asthma are recurrent or chronic infections of the bronchi often secondary to chronic infections of the paranasal sinuses tonsils or adenoids The sinusitis is usually of the chronic hyperplastic type with purulent secretions only during the more acute phases and is often accompanied by mucous polyps in the nasal cavity or within the sinuses Cultures of the secretions of the respiratory system in such cases usually show a mixed growth with pneumococcus *Streptococcus viridans* and hemolytic *Neisseria catarrhalis* *Klebsiella pneumoniae* and *Hemophilus influenzae* the most common organisms Only occasionally can the etiological importance of a single organism be clearly established

The role of allergy in asthma due to respiratory infection is less obvious than in extrinsic asthma but there is considerable evidence that infective asthma results from

FIG 46

specific hypersensitivity to the bacteria present. The asthma may continue severe at times when the infection is in a relatively quiescent chronic stage. The symptoms and clinical findings are similar in infective and extrinsic asthma including the abundance of eosinophils in blood and sputum. The personal or family history of other diseases due to extrinsic allergy is almost as frequent in infective asthma as in the extrinsic type. Skin tests with the available bacterial antigens rarely give immediate urticarial reactions comparable to those produced by pollens and other extrinsic antigens but confirmatory evidence of hypersensitivity is occasionally furnished by the occurrence of an asthmatic attack after the injection of bacterial antigens (usually those derived from cultures of the patient's own secretions) either intracutaneously for skin tests or subcutaneously in attempts at immunization.

Although the distinction between extrinsic and infective asthma is useful in the discussion of diagnosis and treatment, it is important to remember that many if not most asthmatic patients are affected both by extrinsic allergens and by infective factors. Studies of the etiology of a case of asthma should attempt an evaluation of the importance of both extrinsic and infective causes rather than simply classification in one group or the other.

Once the asthmatic pattern of reaction has developed through allergy to extrinsic agents or infection, paroxysms of asthma may be precipitated by many factors unrelated to the original causes. Such secondary factors include emotional stress, changes of temperature and humidity, irritating fumes or smoke, strong odors and physical exertion. These factors may be the obvious precipitating causes of individual attacks. Their recognition and control play

an important part in therapy and in occasional cases in which the underlying allergic or infective basis is obscure or resistant to treatment may constitute the main approach. However, there is little evidence that true bronchial asthma arises purely from them, and when the allergic or infective factors are determined the most satisfactory results usually come from treatment directed at the primary causes. In asthma primarily due to extrinsic allergens, acute respiratory infections may be a secondary factor precipitating attacks. Here also the best results are obtained by treatment directed at the underlying primary cause.

**Incidence.** Asthma is a common disease ranking high among the causes of disability in America and Europe. Apparently all races are susceptible. The incidence in the two sexes is essentially equal and it may occur at any age from early infancy to old age. The onset of extrinsic asthma usually occurs in the first four decades of life; in infective asthma may begin at any age but more often begins in middle age.

**Morbid Anatomy.** The lungs of patients dying during asthmatic attacks are voluminous, distended and less elastic than normal. The lumina of many of the smaller bronchi are occluded by thick, tenacious mucoid secretions. The bronchial mucosa and submucosa are thickened. Microscopic sections show the alveoli to be distended with thinning and rupture of septums. Isolated areas of atelectasis may be present. The bronchial epithelium usually shows many goblet cells and the mucous glands in the submucosa are large and active.

**Pathological Physiology.** In extrinsic asthma the hypersensitivity is mediated by the skin sensitizing antibody demonstrable in the blood serum by the Prausnitz-Kustner reaction and also present in the bronchial tissues and skin. Contact of the sensitized mucosa with the antigen which is direct in the case of inhaled allergens and through the blood stream in the case of ingested antigens elicits an antigen-antibody reaction in the tissues. The exact immunological mechanism of infective asthma has not been established but for the reasons mentioned previously an antigen-antibody reaction is believed to be involved.

The immunological reaction gives rise to a physiological reaction in the bronchi similar to the nasal reaction in hay fever. The lumina of the smaller bronchi are greatly narrowed by swelling of the mucosa and submucosa and by spasm of the bron-

chial muscle. The narrowed lumina are further obstructed by the secretion of thick tenacious sputum from the bronchial glands.

Schild and associates have shown that bronchial muscle excised from the asthmatic patient releases histamine and contracts when exposed to the specific antigen and that this contraction is not inhibited by atropine. This suggests that histamine is the chief intermediary between the immunological and physiological reactions although acetylcholine and serotonin may also be involved.

In patients subject to asthma attacks similar to those occurring spontaneously may be induced by the administration of either histamine or Mecholyl. The same doses of these agents have no effect on normal persons.

Although it is apparent that spasm of the bronchial muscle may occur independently of nervous control, the reaction in the intact patient is influenced by the autonomic nervous system and by adrenal hormones.

Many writers have suggested that reflexes stimulated by irritation of the nasal passages may produce asthma, and the influence of psychogenic factors in producing certain attacks in susceptible persons appears to be well established. However, surgical procedures attempting to prevent asthma by excision of the autonomic nerve fibers supplying the bronchi have not been successful, indicating that the nervous factor is rarely predominant. It has been suggested that psychogenic factors may produce asthmatic attacks through causing hyperventilation, which in itself may precipitate an attack in a susceptible person.

The narrowing of the bronchial air passages and further obstruction by mucoid sputum greatly hamper the ventilation of the lungs in both the inspiratory and expiratory phases. Increased respiratory effort with utilization of the accessory muscles of respiration tends to increase the efficiency of inspiration more than that of expiration, so that the lungs tend to become progressively distended with air as the attack progresses, producing an acute emphysema. Spirometric tracings made during even mild asthma show a decrease of the vital capacity with the reserve air component greatly decreased or absent after a forced inspiration. The maximum breathing capacity is markedly reduced, attempts at increased ventilation rapidly increasing the residual air. Aeration of the blood is obviously impaired by the ventila-

tory difficulty and in severe attacks cyanosis may be apparent. The heart is relatively little affected except as pre-existing cardiac disease is aggravated by anoxemia.

Subsidence of the attack follows widening of the constricted bronchi, permitting expectoration of mucous plugs. With the obstruction relieved the lungs rapidly return to normal after an acute attack. However, persistence of even mild asthma over a long period of time may lead to progressive emphysema, which is only partially reversible.

**Symptoms.** In its most typical form asthma occurs in sporadic paroxysms with respiratory function essentially normal during the intervals. Attacks often occur at night but may also follow exposure to a specific allergen, unusual exertion, a sudden change of temperature, a respiratory infection, or excitement. The onset is marked by a sense of suffocation and pressure in the chest, often with a nonproductive cough. Respiration is marked by a wheeze which is often audible to the patient and bystanders. The respiratory rate is little changed, expiration is often prolonged, but the respiratory effort is greatly increased. The patient sits upright or leans forward to secure maximum use of the accessory muscles of respiration. The chest rapidly becomes distended with air and remains in a relatively expanded state at the end of expiration, the following inspiratory effort producing little further expansion. Termination of the attack is usually marked by cough, productive of a considerable quantity of thick, stringy mucoid sputum. Attacks are often followed by pains in the lower chest, apparently resulting from muscle soreness induced by the violent respiratory efforts.

Most attacks subside spontaneously in a half hour to several hours. In certain cases, particularly those in which the asthma follows respiratory infection, the acute attack may persist for days or weeks and recur promptly even if temporary relief has been obtained with suitable medications. Such persistently severe asthma (status asthmaticus) through fatigue, loss of sleep, and inadequate nutrition rapidly debilitates the patient.

A considerable proportion of patients remain in a chronic state of mild asthma with the symptoms barely noticeable at rest but with dyspnea and wheezing apparent after any exertion, a hearty meal, laughing, singing, or emotional excitement. Usually these are patients who have had severe acute attacks but occasionally

the onset of the disease is marked by this chronic state with no severe attacks for months or years

Physical signs of asthma are quite characteristic. The wheezing may be audible with the unaided ear and is very apparent through the stethoscope with sonorous and sibilant rales heard in all portions of the lung fields usually during both inspiratory and expiratory phases. Cyanosis is rarely present in mild cases but may be marked in the more severe attacks. The chest shows signs of acute emphysema with a low relatively immobile diaphragm and decreased cardiac dullness.

When examined a few hours after cessation of an acute attack the chest may be amazingly normal. However in many other cases the persistence of mild chronic asthma may be manifested by sibilant or sonorous rales heard chiefly at the lung bases and brought out by cough or forced expiration.

**Diagnosis.** The diagnosis of bronchial asthma consists of two steps: first the differentiation of asthma from other diseases causing dyspnea and second the determination of the causative agents producing asthma in the particular patient.

The differential diagnosis is rarely difficult if the patient is seen during an acute attack. The dyspnea, the presence of sonorous and sibilant rales throughout the chest, the thick tenacious mucoid sputum and the history of periodic attacks are very characteristic. A history of asthma and other allergic diseases in the family or of previous allergic disease in the patient is valuable contributory evidence.

**Laboratory examination of the sputum.** Shows distinctive features which are confirmatory evidence. The gelatinous globules when smeared on a slide are found to be elongated spiral casts of the smaller bronchi (Curschmann's spirals). Also visible with the microscope are Charcot-Leyden crystals, elongated pointed octahedral crystals varying in length from 20 to 40  $\mu$ . Streaks of blood may be visible in the sputum during severe asthma but the occurrence of real hemoptysis is rare and suggests the possibility of some other disease. In stained smears eosinophils are seen to comprise a large proportion of the cells. When asthma is associated with acute respiratory infection the sputum is intermediate in character between that of simple asthma and the purulent sputum of bronchitis and some of the typical features may be lacking.

Examination of the blood usually shows

a moderate increase in the proportion of eosinophils ordinarily 5 to 8 per cent but occasionally 30 per cent or higher in severe infective asthma.

Roentgenograms of the chest show no features characteristic of asthma. There may be a moderate increase of the bronchovascular markings and in advanced cases some degree of emphysema is usually apparent. They are valuable however to rule out disease of the lung parenchyma, cardiac hypertrophy and tumors causing pressure on the trachea or bronchi.

The wheezing rales of asthma are usually present throughout the chest during the attack although the sounds may be temporarily suppressed in one area if plugging of a bronchus with mucus has produced atelectasis. The persistence of sonorous or sibilant rales limited to one portion of the lungs is suggestive of bronchial obstruction by a tumor, foreign body or endobronchial tuberculosis. In such cases roentgenograms are of great value but when the differentiation between bronchial asthma and a local obstruction of the air passages is difficult, bronchoscopy is indicated.

Sonorous and sibilant rales are often heard in patients with acute bronchitis; in such cases dyspnea is not a significant symptom and the sputum does not show the characteristic features of asthma. Differentiation during the first attack is not always easy and it is important to remember that recurrent attacks of acute bronchitis with increasingly severe dyspnea often mark the development of true bronchial asthma. A sharp distinction between chronic bronchitis and mild chronic asthma also is often not possible. Many patients with chronic bronchitis show a degree of wheezing dyspnea with typical physical signs of asthma and are benefited by therapy appropriate for asthma. Such a condition is justifiably described as *asthmatic bronchitis*.

Dyspnea due to heart disease only occasionally has the wheezing character of bronchial asthma and sonorous and sibilant rales if present are usually overshadowed by moist or crepitant sounds. When severe attacks of cardiac dyspnea occur at rest other evidences of heart disease are usually apparent. Since both asthma and hypertensive or arteriosclerotic heart disease are common in elderly persons the coexistence of the two conditions is not unusual and the symptoms may be intermingled to a confusing degree.

When the diagnosis of bronchial asthma

has been established determination of the etiological factors is essential for rational long term management. This requires meticulous inquiry as to the time place and circumstances in which attacks have occurred and the potential allergens to which the patient is exposed. Asthma during the spring and summer months suggests pollens or mold spores and a precisely dated season may indicate one particular pollen. (See section on Hay Fever for discussion of pollen seasons.) Attacks limited to the winter months obviously suggest an infective cause although bedding such as a down quilt used only during the cold weather may be the cause. Persistence throughout the year suggests household contacts, pets or bedding but may also be due to chronic respiratory infection. An observed relationship to certain foods or drugs or to acute respiratory infection is important. Certain occupations involve exposure to distinctive antigens: the farmer to animal danders, feeds and fertilizers; the baker to flour and so forth. Attacks occurring in certain houses may be due to pets, to bedding or upholstered furniture or the molds and fungi they harbor. In evaluating the history one should remember that a majority of patients with asthma are affected by more than one factor; a large number by both extrinsic and infective factors.

The properly taken history usually calls attention to possible antigens but except in cases of pollen asthma only occasionally completely establishes the cause. Sensitivity is demonstrated by testing the skin with the possible allergens suggested by the history. These skin tests may be carried out by either the scratch or intracutaneous method as described in the two preceding sections.

In the usual case of asthma intracutaneous tests are made with extracts of pollens, animal danders and orns containing 100 protein nitrogen units per ml. cottonseed, kapok, flaxseed and fish glue. 10 units and molds, house dust, feathers, silk, wool and pyrethrum. 1000 units. Foods are tested in the 1000 unit strength except for egg and mustard 100 units. If the history suggests violent sensitivity to one or more antigens these are tested first in a concentration one tenth as great. Not more than six intracutaneous tests are done at one time but if no undue reaction is noted after ten minutes further groups of six may be done to a total of eighteen or twenty four at one sitting. Antigens which give doubtful one plus or two plus reac-

tions when tested in dilutions of 10 or 100 units per ml. should be retested with successive tenfold increases of concentration until three plus reactions are obtained or until a concentration of 1000 units per ml. is reached.

If skin tests are properly performed and read the positive reactions indicate sensitization of the skin to the antigens tested. The importance of these substances in the actual production of clinical asthma must be judged from correlation of the skin reactions with the history of the case. A one plus or two plus reaction which explains the observed time and circumstances of attacks is of value while a strong reaction to a substance with which the patient has little or no contact is of limited significance. In general skin reactions to inhaled antigens which come into direct contact with the sensitized mucosa are of greater significance than skin reactions to foods which are greatly altered by cooking, digestion and metabolism before reaching the bronchi through the blood stream. Positive skin reactions to foods are regarded as suggestive evidence of their etiological importance in asthma and the final evaluation is by clinical judgment based either on the past history or the observed results of eliminating the foods from the diet. Not only may foods giving positive skin reactions prove innocuous when eaten but occasionally foods showing negative skin reactions cause asthmatic attacks usually delayed several hours after ingestion and presumably due to the production by digestion of an antigen not present in the original material. This situation while rare obviously calls for careful observation rather than acceptance of skin tests as the final criterion.

Evaluation of infective factors in the causation of asthma is not always easy. Attention may be directed to this possibility by the absence of skin reactions to all probable extrinsic allergens but in many cases both extrinsic allergens and infection are important. As previously noted the onset of asthma after the age of 40 years is statistically suggestive of infective asthma at any age the coexistence of chronic sinusitis particularly of the hyperplastic type or of nasal polyps indicates a potential infective factor. Skin tests with bacterial antigens have not proved a reliable criterion except in those cases in which an exacerbation of constitutional symptoms is inadvertently produced. In patients requiring hospitalization the persistence of asthma after three or four days

in an environment which eliminates insofar as possible contact with inhalant allergens usually indicates the presence of endogenous usually infective factors

As previously mentioned asthmatic patients are often made worse by nonspecific secondary factors such as changes of temperature and humidity irritating fumes and odors acute infections exertion excitement and emotional stress These conditions rather than changes in exposure to antigens may be the actual precipitating causes of individual attacks Their importance which can be judged only by careful inquiry into the circumstances of occurrence of exacerbations must be evaluated if treatment is to be successful However obvious as their relationship may be they should be recognized as secondary influences and not confused with the fundamental allergic or infective causes of the asthmatic state

**Prognosis** Asthma is a chronic disease with a marked tendency to periodic recurrence over a period of many years unless the causative factors are recognized and satisfactorily handled Present methods of treatment do not afford the prospect of actual cure Approximately 25 to 30 per cent of the cases beginning in early childhood undergo spontaneous recovery during adolescence but since an essentially equal number become worse during the same period withholding treatment in hope that the condition will be outgrown is not justified During adult life the tendency to spontaneous recovery is much less marked and there is a greater probability of the attacks becoming progressively more frequent and prolonged with the remission less complete and with nonspecific factors playing an increasing part in the causation With repeated attacks over a period of years asthma originating as a strictly seasonal reaction to a specific pollen may be prolonged progressively beyond the pollen season and gradually enter into a chronic state lasting throughout much of the year Infective asthma in elderly patients is particularly apt to become chronic Persistent asthma from any cause is apt to produce pulmonary emphysema and permanent ventilatory disability

The danger to life in the average attack is slight although death occasionally occurs in acute attacks caused by allergy to rapidly absorbed drugs such as aspirin or in attacks resulting from injection of an overdose of antigen in testing or treatment However in severe status asthmaticus with persistent cyanosis failing to respond to

corticotropin or cortisone the mortality is considerable Some deaths are attributable to depression of respiration and cough by injudicious use of sedatives but many are entirely uninfluenced by attempts at therapy

**Treatment** Therapy of asthma comprises three types of efforts (1) symptomatic relief of the attack (2) control of specific causative factors (3) general care of the patient

**Symptomatic Relief** During the acute attack relief may usually be attained with epinephrine 1:1000 injected subcutaneously or intramuscularly Since patients vary both in tolerance and response best results are obtained with 0.3 to 0.5 ml (0.1 to 0.2 ml for infants or small children) repeated if necessary every five or ten minutes for two or three doses This treatment will terminate mild attacks but in more persistent cases may be required every two or three hours Frequent repetition may be avoided by the use of a slowly absorbed form of epinephrine such as epinephrine in oil 1:500 1 ml intramuscularly every six to twelve hours For the ambulatory treatment of patients with frequent mild attacks inhalation of an aerosol of epinephrine 1:100 or isopropylarterenol (Isuprel) 1:200 from a suitable nebulizer is a convenient measure often producing prompt relief Also effective in mild attacks and having the advantage of oral administration is ephedrine 25 mg every four hours if necessary The stimulating effects of ephedrine may be minimized by combination with a mild sedative such as phenobarbital 15 mg All drugs of the epinephrine group should be used cautiously in patients with coexisting hypertension heart disease or hyperthyroidism

In acute attacks not relieved by epinephrine aminophylline 0.25 to 0.5 gm injected slowly intravenously is often effective and may be repeated after two to three hours if necessary A slower but more prolonged effect may be obtained by administering aminophylline 0.5 gm (0.25 for children) by rectum every eight to twelve hours if needed either as a suppository or dissolved in 20 to 30 ml of water Oral use of aminophylline in asthma is limited by the tendency of adequate doses to produce nausea However a combination of aminophylline 120 mg ephedrine 25 mg and phenobarbital 15 mg every four hours if necessary is useful for mild attacks

Sedatives are useful adjuncts in the relief of severe asthma but the danger of

depressing respiratory function precludes their employment as the principal therapy Demerol is preferable to morphine and may be used in doses of 50 mg repeated once after four hours if necessary. The barbiturates and tranquilizers in moderate doses are valuable. If strong sedation is needed ether 60 ml in 120 ml of oil by rectum is relatively safe. Codeine 15 mg or elixir of terpin hydrate with codeine 3 ml every four hours may be used to control excessive cough.

In persistent asthma expectorants are often valuable to facilitate discharge of tenacious mucoid sputum. The most effective is potassium iodide 0.6 gm three times a day after meals. Ammonium chloride in the same doses may be tried by patients who do not tolerate iodide.

In severe asthma which is not readily controlled by medications oxygen administered by tent, nasal catheter or mask is a useful supportive measure. Positive pressure is of value only in the inspiratory phase; the ordinary masks applying pressure during the expiratory phase are not helpful.

If acute asthma persists for several days or fails to respond to the medications previously mentioned, the use of corticotropin, cortisone or prednisone is of value for temporary relief. In the most severe cases corticotropin 15 to 20 units is given in an intravenous drip of 1 liter of 5 per cent glucose solution over a period of eight hours repeated daily if necessary. In less urgent situations corticotropin 40 units in gelatin is injected intramuscularly daily or cortisone 50 mg or prednisone or prednisolone 10 mg given by mouth every six hours. As soon as relief is obtained the dose is reduced by 25 to 50 per cent and then rapidly tapered off over a period of four to five days. These drugs must be used with caution in patients with heart disease, diabetes, peptic ulcer or mental disease and are generally contraindicated in patients with pulmonary tuberculosis or pregnancy. Careful observation for evidence of fluid retention is essential, particularly if cortisone or corticotropin is continued for more than a week. Salt intake should be restricted and potassium chloride given in 10 gm doses three to five times daily.

In severe chronic asthma which cannot be controlled by other symptomatic or specific treatment the use of small maintenance doses of prednisone or prednisolone over a prolonged period may be considered if the disability caused by the asthma outweighs the potential risks of a prolonged

hyperadrenal state. After the symptoms have been controlled by the usual doses of prednisone or prednisolone the dose is reduced to the minimum which will maintain a satisfactory degree of relief, usually not exceeding 5 mg every eight to twelve hours. Patients receiving such treatment should be kept under close supervision and intercurrent infections treated promptly.

Numerous other measures are of some value in various phases of asthma. In persistent severe asthma with retention of thick sputum bronchoscopic aspiration is sometimes effective. Fever therapy usually produced with intravenous typhoid vaccine has been used in status asthmaticus but is rarely as effective as cortisone or corticotropin. For the relief of mild attacks inhalation of the fumes of burning stramonium leaves is reasonably effective. The antihistamine drugs are also mildly efficacious but offer no advantage over ephedrine and aminophylline.

**Specific Treatment.** Satisfactory handling of asthma over the long term requires the control of the causative factors. Asthma due to extrinsic antigens is best treated by the avoidance of contact with the antigen when possible. Elimination of household pets, feather pillows and so forth generally produces more satisfactory relief than any attempt at immunization. In the case of occupational allergens such as flour in bakers' asthma a trial of injection treatment may be warranted but usually a change of occupation eventually proves necessary. Avoidance of windborne pollen is possible as a temporary measure either by a trip to a location free of the offending plant or by air filtration. But continuation of the patient's usual residence and activities requires injection treatment. Contact with house dust may be minimized by stripping the bedroom of carpeting, drapes and heavy furniture and by careful cleaning but coincident injection treatment is usually needed.

Treatment by injections of antigen variably described as immunization, desensitization or hyposensitization is generally indicated in asthma due to house dust, mold spores or pollens and may be advisable in the cases due to other protein antigens with which the patient cannot completely avoid contact. The general principle is to begin treatment with an injection of no more than twice the actual amount of antigen injected in the intracutaneous test giving a moderate (two plus) or marked (three plus) skin reaction and to proceed with injections once or twice a

week gradually increasing the dose aiming to reach a dose approximately 500 times the initial one after about sixteen injections. The schedules included in the section on Hay Fever are generally applicable to the treatment of asthma but in patients highly sensitive to nonseasonal allergens it may be necessary to proceed somewhat more slowly if the patient is constantly exposed to the antigen while treatment is progressing. In the case of house dust allergen the strengths of available solutions may not permit as great a range of dosage as with pollens. Usually a top dose of 0.5 to 0.8 ml of the strongest available dust extract is adequate.

The injections are given subcutaneously on the lateral aspect of the upper arm or thigh with a rubber tourniquet and epinephrine hydrochloride 1:1000 solution at hand in case of an excessive reaction. After the injection the patient should be kept under observation for twenty minutes to observe the local reaction and to treat any constitutional symptoms that may develop. (See section on Hay Fever.)

While the antigen dosage schedules serve as a guide they must be modified in accordance with the individual patient's reaction. As the dosage progresses a local reaction manifested by redness and swelling 2 to 4 cm in diameter usually occurs at the site of injection and need not cause a change in the program of doses. If the local reaction is uncomfortably large or persists for more than thirty-six hours the same dose should be repeated at the next injection rather than progressing according to the schedule. When this dose no longer produces an excessive reaction one may increase as indicated in the schedule or somewhat more cautiously. If an injection produces a constitutional reaction the following dose should not exceed one-half the dose producing the reaction and should not be given sooner than one week later. Subsequent increases should be about one-half as large as those listed in the schedules with careful observation of the local reaction each time. If it becomes apparent that the patient cannot tolerate a larger dose the schedule is abandoned and treatment continued with a dose one-quarter to one-third less than that which produces an excessive reaction.

The maintenance dose either the top dose indicated in the schedule or that comfortably tolerated by the patient is repeated every two weeks. If the symptoms are completely controlled the interval between injections may be increased to three

or four weeks. The individual doses remaining the same. Treatment may be expected to be necessary for several years or indefinitely. Once a year the skin tests with antigens used in treatment are repeated and if some have become essentially negative those antigens may be discontinued while carefully observing the patient for recurrence of symptoms.

*Treatment of Infective Asthma.* Infections of the respiratory system believed to be causative factors in asthma should be treated vigorously with available medical and surgical measures. During the more acute stages the antibiotics penicillin, tetracycline and streptomycin are often effective. It should be noted that asthmatic patients are particularly susceptible to severe penicillin reactions. Adequate drainage of infected paranasal sinuses should be maintained by local treatment with excision of nasal polyps if necessary. If recurrences of infection are very frequent prophylactic doses of benzathine penicillin 600,000 units every two weeks or of a sulfonamide such as sulfisoxazole (Gantrisin) 0.5 to 1.0 gm twice a day may be given during the fall and winter months.

Injections of bacterial vaccines or filtrates are often of value in recurrent infective asthma but must be given cautiously in patients highly allergic to bacterial products. General reactions with exacerbations of asthma often delayed one or two days after the injection and lasting several days are easily provoked by excessive doses. If the concentrated vaccine is 1 per cent by volume or approximately 5 billion organisms per cubic centimeter the first dose should not exceed 0.1 ml of a 1:1000 dilution and subsequent doses at weekly intervals may be gradually increased up to 0.1 to 0.2 ml of the concentrated material in a manner similar to that employed for pollen antigens.

If the sinuses show evidence of chronic disease and conservative measures are not effective consideration may be given to surgical measures. Since the thickened membrane of the sinuses is the site of infection satisfactory surgical treatment requires widely opening all the sinuses shown by roentgenograms to be involved and complete removal of the hyperplastic or polypoid membrane. When such operations are thoroughly performed the results are favorable in a sufficient proportion of cases to warrant their employment in cases not otherwise relieved.

*General Measures.* The general care of the asthmatic patient involves chiefly the

avoidance of those secondary factors which are apt to aggravate asthma regardless of the primary cause. Extremes of cold and humidity should be avoided particularly outdoor exertion in cold damp weather. Exposure to respiratory infections should be avoided as far as reasonably possible. For these purposes spending the winter in a warm dry climate may be helpful. Smoking should be avoided or restricted to a minimum. Physical exercise should be limited to the tolerance of the patient and the more violent forms of exertion should be avoided. Causes of emotional stress should be eliminated when possible. Psychotherapy is only occasionally needed.

In patients with chronic asthma who are developing emphysema breathing exercises which stress complete expiration rather than deep inspiration are helpful both to increase ventilatory efficiency and to lessen the development of chest deformity. Manual pressure on the lower ribs and diaphragm during expiration is helpful in emptying the chest.

Maintenance of an optimistic mental state is important. Needless to say few things will contribute more to this attitude than the combination of effective and readily available symptomatic relief with a logical plan for determining and coping with the causative factors.

#### Drug Allergy

**Definition.** Drug allergy is a general often loosely used term for a multiplicity of sensitivity reactions including skin eruptions, edema, arthritis, lymphadenopathy, hematological abnormalities, fever, and periarthritis which occur during or following the administration of a variety of therapeutic agents. The symptoms bear no rela-

tion to the primary pharmacological properties of the drug concerned and resemble in important respects the manifestations of serum sickness. It is generally assumed that the reactions are due to the presence of antibody against the drug itself or against an antigenic conjugate between the drug and a protein in the blood or tissues. This assumption is based in part on experimental studies by Landsteiner and his associates of the antigenicity of simple chemicals and there is some evidence to support it in several types of reaction in human beings. However, in actual practice the majority of reactions cannot be proved to involve an antigen-antibody mechanism. Some of the manifestations attributed to allergy such as agranulocytosis, hemolytic anemia, and hepatitis cannot be reproduced in experimental animals nor can the presence of antibody be demonstrated in patients. The designation of such reactions as drug allergy should therefore be regarded as tentative.

**Incidence.** Although allergic reactions have been reported to occur with almost every medication in common use, there are large differences in the capacity of different drugs to produce reactions. Important differences also exist in the susceptibility of different persons. Patients with a history of other allergic diseases are more apt to develop drug reactions. As an example, aspirin rarely causes sensitization in normal persons but patients with bronchial asthma are remarkably prone to exhibit asthma or urticaria after taking the drug. The incidence of penicillin reactions has been stated to be as high as 10 or 15 per cent but there is a great variation in different reports depending on the degree of purity of the penicillin, the presence of other substances in the vehicle employed, the route of injection, the duration of treatment and the amount administered. At the University of Minnesota Hospitals 2.5 per cent of a recent series of 562 patients developed reactions to penicillin consisting of skin eruptions and mild fever; no severe reactions occurred.

Certain drugs such as phenylethylhydantoin (Nirvanol), arsphenamine, and thiouracil are known to produce sensitivity reactions in a high proportion of patients. "Nirvanol sickness," a syndrome closely resembling serum sickness, has been reported to occur in all patients given large doses of the drug.

The incidence of drug allergy depends to some extent on prior exposure to the drug although this seems to be much less im-

portant than in serum sickness. Reactions to the sulfonamides and penicillin are more likely to occur in previously treated patients but many occur at the first contact with the agents.

**Pathogenesis** Landsteiner and his associates made a series of important experimental observations which have led to an interesting concept of the mechanism of drug allergy. It was shown that animals could be specifically sensitized to simple chemical compounds such as picric acid or dinitrochlorobenzene by repeated exposure to the substances or by the injection of conjugates of the chemicals with protein. Sensitization with chemical alone was found to involve a union *in vivo* with body protein yielding antigenic complexes whose immunological specificity was determined by the chemical hapten. Antibody formed against such complexes was capable of reacting either with the chemical alone or with the chemical protein conjugate but not with the protein.

It has been postulated that a similar mechanism may account for drug allergy in man. The administration of a drug would under this theory be followed by the formation of a union between tissue or blood proteins and the drug or a breakdown product of the drug. Antibody produced against the conjugate would subsequently react with the drug itself (or with the breakdown product) and also with protein drug conjugate formed after readministration of the drug. Moreover, since specificity of the antibody is determined by the structure of the chemical hapten, it is possible that sensitization would also occur to closely related substances.

If this concept is correct the mechanism of drug allergy would involve several variable factors which might affect the incidence of reactions and also the tissue sites involved. The capacity of a drug to unite with body protein and differences in the degree of union in different individuals would be of much importance. If the complex of drug and body protein were soluble and rapidly absorbed the sensitivity would probably be of the immediate anaphylactic type. If the protein constituent of the complex were confined to a particular tissue or cell and not removed or absorbed reactions of the local delayed type would occur. Furthermore, if the haptens were not the drug itself but a metabolic breakdown product, individual variations in the metabolism of the substance would play a role in the incidence of drug allergy.

Further investigation of the problem in

man has been delayed because of the absence of satisfactory methods for detecting the presence of antibody in almost all types of drug allergy. Ackroyd has described a complement fixation reaction with the serum of patients with thrombocytopenia due to Sedormid sensitivity in which the antigen consists of a mixture of Sedormid and platelets; no fixation of complement occurred with Sedormid alone or with platelets alone. Leftwich reported that sulfonamide sensitivity could be detected by an intradermal injection of serum containing the sulfonamide but not with solutions of sulfonamide alone, implying that a protein-sulfonamide complex was necessary for the production of a skin reaction. However, a large number of investigators have been unable to demonstrate antibody in various types of drug allergy by any of the available methods.

**Pathology** Death is a rare event in drug allergy and there is little information concerning the pathology of the disease. Rich and his associates found typical vascular lesions of periarteritis nodosa similar to the changes in experimental serum sickness in several patients with severe reactions to sulfonamides. Similar lesions have been described in patients dying with hypersensitivity reactions to penicillin, iodine, thiourea, and Dilantin.

**Symptoms** The most common type of drug reaction is a mild systemic illness with the clinical features of typical serum sickness, including erythematous and urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. Such reactions may occur during treatment with penicillin, the sulfonamides, chlortetracycline, streptomycin, aspirin, barbiturates, Dilantin, thiouracil, iodides, and many other drugs. The disease usually begins between six and twelve days after the start of medication and lasts two or three days. More prolonged reactions may occur if the drug is not withdrawn promptly.

Immediate anaphylactic type reactions to drugs are uncommon but occasionally occur in patients with extreme degrees of sensitization. Persons with other allergic diseases are more susceptible to such reactions. The symptoms, which are similar to those of an acute serum accident, may appear within a few minutes after injection of certain drugs. Some of the acute fatal reactions to penicillin are of this type. Procaine produces a similar reaction in susceptible individuals; it is not known whether this is based on allergy or a pharmacological idiosyncrasy.

Isolated symptoms are common in drug allergy. Patients may develop only fever without other allergic manifestations usually during the second week of treatment with penicillin, sulfonamides, arsphenamine, iodides, and barbiturates. The fever continues until the drug is discontinued and will usually reappear with a second administration. Other isolated signs of drug allergy may be skin eruption, conjunctivitis, lymphadenopathy, abdominal pain, and vomiting and pharyngitis. Proctitis and diarrhea are frequent complications of treatment with chlortetracycline, oxytetracycline, and chloramphenicol, but there is no evidence that this represents an allergic reaction.

Other forms of skin eruption differing from the erythema and urticaria of serum sickness occur as reactions to certain drugs. *Exfoliative dermatitis* is a complication of treatment with gold, arsphenamine, penicillin, iodide, quinine, Dilantin, and the sulfonamides. *Fixed eruptions* which recur in the same skin area on readministration of the drug are caused by numerous drugs including barbiturates, phenol, phthalein, bromide, iodide, sulfonamides, and Bromsulfalein. *Erythema nodosum*, *photosensitization*, and *contact dermatitis* have occurred as reactions to various drugs.

The hematological reactions to drugs are of major importance. The most frequent and serious of these is *agranulocytosis*, which may occur during treatment with the sulfonamides, thiouracil, aminopyrine, arsphenamine, Butazolidin, and gold. *Agranulocytosis* usually appears during or after the fourth week of continuous treatment; the onset may be earlier in previously sensitized patients. *Thrombocytopenic purpura* has been associated with Sedormid, quinine, quinidine, thiouracil, Mesantoin, and the sulfonamides. *Hemolytic anemia* was a frequent complication of treatment with the older sulfonamide preparations, particularly sulfapyridine and sulfanilamide; hemolysis usually occurred within the first five days of treatment and was not proved to be due to allergy. *Aplastic anemia* is an infrequent event during therapy with chloramphenicol, gold, trimethadione, and the sulfonamides; the allergic basis for this complication is also open to question.

*Periarteritis nodosa* has occurred during treatment with the sulfonamides, penicillin, iodine, thiourea, and Dilantin. The studies of Rich and his associates indicate that this disease may represent a basic type

of hypersensitivity reaction to many anti-genic substances.

Severe liver damage is sometimes produced by arsphenamine, cinchophen, and the sulfonamides. There is no direct evidence to indicate an allergic basis for such reactions. The same is true for *peripheral neuritis* and *hemorrhagic encephalitis*, which are rare complications of drug therapy. It is possible that the latter diseases may occur as manifestations of *periarteritis nodosa*.

Longcope has emphasized the importance of renal involvement in drug allergy. Acute *hemorrhagic nephritis* has appeared during reactions to Nirvanol, arsphenamine, and the sulfonamides.

A syndrome resembling *lupus erythematosus* with arthritis, fever, polyserositis, and hyperglobulinemia has been described in patients receiving prolonged therapy with hydralazine (Apresoline) for hypertension. The plasma of these patients produced the characteristic alteration of leukocytes which occurs in lupus (the LE phenomenon) which has also been observed in allergic reactions to penicillin.

**Diagnosis.** Discontinuation of the drug in question is the safest and most reliable diagnostic measure, and the prompt disappearance of symptoms permits a presumptive diagnosis of drug allergy. There are no specific diagnostic tests of proved value. If symptoms recur when the drug is administered a second time, the diagnosis becomes more certain, but this procedure is rarely justified. Skin tests and attempts to demonstrate antibody by test tube or passive transfer are negative in most instances. Eosinophilia may occur in patients with skin eruptions, and the LE phenomenon may be present in severe systemic drug reactions.

**Treatment.** In most cases the symptoms are completely relieved when the medication is stopped, and no other treatment is required. In mild reactions, and when the therapeutic agent is of vital importance, the medication may be continued under close observation, but if another drug can be substituted this should always be done. *Agranulocytosis* should be treated with appropriate antibiotic therapy to control infection. Benadryl or Pyribenzamine in a dose of 50 mg every four hours may relieve the itching and discomfort of skin eruptions. Epinephrine should be given for immediate anaphylactic reactions, in a dose of 0.5 to 1.0 ml of the 1:1000 dilution by subcutaneous injection; it is also useful for temporary relief of urticaria.

Corticotropin and cortisone may be of great value in the treatment of severe reactions. Either of these hormones in a dose of approximately 100 mg daily should be used in cases of exfoliative dermatitis prostrating or extremely painful systemic reactions and inflammatory reactions involving the eye. Considerably larger doses of cortisone or hydrocortisone may be required for a short period of time in severe cases.

## Serum Sickness

**Definition.** Serum sickness is the systemic reaction which follows an injection of foreign serum and is the result of interaction between specific antibody and an antigenic protein or proteins contained in the injected serum. In its fully developed form the illness is characterized by skin eruptions, fever, lymphadenopathy, arthralgia, abdominal pain, nausea and vomiting. It may occur at any time within two weeks after the injection of serum. In persons previously sensitized to the foreign protein the antibody response is accelerated and the incubation period is several days shorter than in normal persons. With sufficiently high degrees of preexisting sensitization an extremely severe and some times fatal reaction may occur immediately after injection; such reactions are commonly referred to as *serum accidents*.

**Incidence.** The introduction of prophylactic toxoids and specific antibacterial therapeutic agents has greatly reduced the use of serum therapy and therefore the incidence of serum sickness. The disease now occurs as an occasional complication

of the management of diphtheria, tetanus, clostridial infections, botulism and snake venom poisoning. The incidence of reactions is greater after injections of whole horse serum than when highly purified antisera are employed, presumably because of the reduced number of different antigens in the latter preparations.

Neither age, sex, state of health nor route of injection appears to influence the incidence of serum sickness. There is some evidence that Negroes and American Indians are less susceptible than white persons. The major factors which determine the incidence as well as the severity of the disease are (1) the amount of serum injected and (2) the previous immunological status of the patient.

When the amount of serum is 10 ml or less, serum sickness occurs in approximately 10 per cent of patients. The incidence rises to 90 per cent when 100 ml or more are injected. Patients with a history of previous injections of the same foreign serum may be expected to develop serum sickness more frequently and in greater severity than normal persons.

Instances of serum sickness have occurred following transfusion with human whole blood. Some of these are due to passive transfer of antibody against antigens to which the recipient of the transfusion is exposed; others have been shown to be caused by the presence of antigens in the transfused blood to which the recipient is hypersensitive.

A syndrome which is indistinguishable from serum sickness is known to occur during the course of treatment with certain drugs and it is possible that a similar immunological disturbance is involved. This type of reaction is discussed in the section on Drug Allergy.

**Pathogenesis.** The basic mechanisms which are responsible for serum sickness have received much investigation in man and in experimental animals. It is known that within six to twelve days after an injection of foreign protein in the rabbit precipitating antibody appears in the blood. In subjects previously exposed to the same antigen, antibody may appear within the first two or three days. Simultaneously with the appearance of antibody, the foreign protein which has been detectable in the blood until this time disappears completely. It has been suggested that a precipitation reaction between antigen and antibody followed by clearance of the conjugate from the blood may be occurring during this period. The mechanism of removal and

destruction of the antigen is not understood. The level of serum complement undergoes a sharp reduction during the time of appearance of antibody and disappearance of antigen from the blood perhaps this is a manifestation of fixation of complement *in vivo*.

Comparable events have been observed in human serum sickness and it is generally accepted that a causal relationship exists between the antigen-antibody interaction and the symptoms of the disease. A correlation has been shown to exist between the occurrence of serum sickness and the degree of antibody formation although the antibody is usually not demonstrable until late in the course of the illness. Patients who do not develop serum sickness have little or no demonstrable antibody and the antigen is demonstrable in the circulating blood for much longer periods of time. As to the actual events which lead to tissue damage in serum sickness there is very little information. It has been suggested that injury to endothelial and smooth muscle cells may be caused by the local release of histamine, acetylcholine or proteolytic enzymes; direct proof for these hypotheses is lacking.

Recurrences of symptoms sometimes occur after apparent recovery from serum sickness. These relapses, which are usually seen in patients given whole horse serum, probably represent successive independent episodes of antigen-antibody interaction involving different antigenic proteins in the serum.

**Pathology.** Serum sickness is almost always a relatively benign, brief illness and very few deaths resulting from the disease itself have been recorded. The most important information concerning the pathological alterations in tissues has been contributed by Rich and his associates who described vascular lesions indistinguishable from those of periarteritis nodosa in patients with serum sickness. Similar arterial lesions have been shown to occur frequently in experimental animals following the intravenous injection of large amounts of foreign protein. On the basis of these observations it has been suggested that periarteritis nodosa and related "collagen" diseases such as rheumatic fever and disseminated lupus erythematosus may be based on an immunological disturbance analogous to serum sickness.

**Symptoms.** The incubation period is usually between six and twelve days after the injection of serum but may be much shorter in previously sensitized persons.

The illness begins with a skin eruption, which may take the form of urticaria, patches of erythema or a diffuse morbilliform rash or combinations of these. Such skin manifestations are the most conspicuous and constant feature of the disease and occur in over 90 per cent of patients. Occasionally petechiae or purpuric skin lesions are encountered. Itching occurs shortly before the skin eruption is obvious and usually persists throughout the illness. It is most bothersome in patients with extensive urticarial lesions. A generalized lymphadenopathy is present in most patients at the time of or just prior to the appearance of the skin eruption. Edema of the face, eyelids, hands and feet occurs in approximately 30 per cent of cases. It is more frequent and severe in children than in adults. Edema of the glottis is in rare instances sufficiently intense to require tracheotomy. Some patients without obvious edema undergo a rapid gain in weight during the period of the disease owing to retention of water. The renal excretion of sodium chloride and water is markedly reduced at this time.

In many patients the disease is limited to the above mentioned manifestations and these disappear within two to three days. In more severely ill patients the skin eruption lasts for a week or longer and on the third or fourth day after onset fever appears with daily elevations of temperature to 101° or 102° F. During the febrile period constitutional symptoms such as malaise, headache, abdominal pain, nausea and vomiting are often present.

Involvement of the joints occurs in approximately 50 per cent of patients with serum sickness, usually beginning two to three days after the appearance of skin eruption. There may be mild arthralgia and some stiffness on movement or less commonly there may be outright polyarthritis resembling the joint symptoms of acute rheumatic fever. Swift and Boots found the joint fluid to be an inflammatory exudate containing numerous polymorphonuclear leukocytes. The earliest joint to be involved is usually the temporomandibular joint and limitation of motion in this joint may be misinterpreted as early tetanus in patients treated with antitetanus serum.

Neurological manifestations sometimes occur in severe serum sickness. Stupor, coma and transient hemiplegia associated with an increase in cerebrospinal fluid pressure have been observed. Optic neuritis may occur as a complication of serum sickness. Peripheral neuritis usually in

volving the cervicobrachial plexus may cause severe root pains in the shoulder girdle and upper extremities with temporary weakness or paralysis of arm muscles.

**Diagnosis** Laboratory studies provide little if any assistance. Patients with serum sickness following injections of horse serum may exhibit elevated titers of heterophile antibody for sheep erythrocytes. Leukocytosis and eosinophilia are uncommon but may occur late in the course of illness. The urine may show slight albuminuria and a few casts but there are no significant evidences of renal impairment. The erythrocyte sedimentation rate is usually normal.

The disease may be mistaken for rheumatic fever if a history of serum administration is unobtainable. In cases of inconspicuous or absent skin eruptions the symptoms may resemble those of complications of the disease for which serum was administered for example tetanus. In general however the typical syndrome of serum sickness is unmistakably recognizable.

**Serum Accidents** The acute immediate shock-like reactions which follow an injection of foreign serum in previously sensitized individuals are in all probability based on the same immunological disturbance as that involved in serum sickness. The early onset and severity of symptoms are due to the existence of antibody at the time of injection of antigen and the situation is quite similar to anaphylactic shock in animals. Within a few seconds after injection the patient may exhibit extreme apprehension, violent itching, sneezing and coughing and asthmatic breathing. Generalized urticaria may appear within minutes. The blood pressure falls and the pulse becomes weak or imperceptible. There may be sudden loss of consciousness accompanied by generalized convulsive seizures. The temperature is usually elevated shortly after the beginning of symptoms. Death can occur within less than ten minutes or after several hours. Patients who survive such episodes usually exhibit other evidences of typical serum sickness during the next few days.

The pathological findings in fatal serum accidents include extensive acute emphysema of the lungs, dilatation of the right ventricle and multiple small hemorrhages in the heart, lungs, kidneys and adrenal glands.

**Treatment** Recognition of hypersensitivity in patients prior to the administration of foreign serum is of the first importance in avoiding serum reactions. All patients should be carefully questioned con-

cerning previous injections of serum. A history of asthma, hay fever or other allergic reactions is an indication for special caution in the administration of serum. All patients regardless of history should be tested for cutaneous and conjunctival sensitivity before undertaking serum treatment. The intracutaneous test may be performed with 0.02 ml of a 1:10 dilution of the serum to be used for the conjunctival test, a drop of 1:100 dilution is employed. If either test is positive the use of serum treatment should be reconsidered in the light of the potential danger involved. If it is imperative that serum be administered, an attempt should be made to desensitize the patient. This may be done by giving repeated injections of small amounts every fifteen minutes starting with 0.1 ml of a 1:100 dilution subcutaneously and doubling the amount with each dose until 1 ml has been given by this route. Intravenous injections are then begun in the same fashion beginning with 0.1 ml and doubling the dose every fifteen minutes until the required amount has been administered.

Serum reactions of the immediate anaphylactic variety are treated with epinephrine which should be available in a syringe whenever serum is injected. A dose of 0.5 to 1.0 ml of a 1:1000 dilution should be given subcutaneously at the first sign of an acute serum reaction and repeated after a few minutes if indicated.

The usual case of serum sickness is a mild self-limited disease presenting few problems of therapy. The itching discomfort associated with urticaria may be temporarily relieved by subcutaneous injections of epinephrine or by the oral administration of Pyribenzamine in a dosage of 50 mg every four hours. Cortisone and prednisone have been used with success in the treatment of allergic reactions to drugs and may be useful in controlling the discomfort in severe or prolonged attacks of serum sickness. Most cases however are so mild that such treatment is unnecessary.

## Contact Dermatitis

**Definition** Contact dermatitis is an eczematous inflammation of the skin resulting from exposure of its unbroken surface to foreign material. It may result either from the primary irritant effect of the causative agent or from a specific acquired allergic sensitization to an agent which is not irritating on first contact. Although these two types of reaction produce similar pathological changes in the skin, the former represents a response of essentially all persons to an obviously toxic agent and the latter is a specific response of a sensitized individual to a substance which does not cause irritation on the first exposure and even after repeated exposure affects only certain persons. It should be noted that many industrial chemicals which in high concentrations act as primary irritants are also active sensitizers in dilutions which are not toxic. Since the primary irritants encountered in the home—lye solvents, strong acids and tincture of iodine—are well known and those used in industry are familiar to workers handling them, it is the allergic type of contact dermatitis which will be discussed here.

**Etiology** The agents producing allergic contact dermatitis must be capable of penetrating the unbroken surface of the skin and eliciting a specific allergic response. Most of the typical antigens which produce other types of allergic reactions are large molecules, proteins or complex carbohydrates. Since these compounds do not readily penetrate the epidermis, they rarely act as causative agents of contact dermatitis. The principal etiological agents are of relatively small molecular size but act as haptens combining with the proteins of the skin and producing conjugates of sufficiently altered immunological specificity to be antigenic to the individual in which they are formed.

The actual causative agents are innumerable and of varied chemical nature. Important examples which may be encountered at home are (1) metals, particularly nickel, chromium and mercury; (2) salts of these and other metals; (3) topical medications, particularly sulfonamides, local anesthetics and antihistamines; (4) cosmetics, nail polish and hair dyes; (5) soaps and detergents; (6) dyes and finishes applied to fabrics, furs or leather; (7) plastics; (8) rubber; and (9) oleo resins of plants, particularly those of the genus *Rhus* (poison ivy and poison sumac).

Chemical workers, photographers, metal workers, beauticians, tanners, nurses and others encounter other agents peculiar to their occupations.

The susceptibility of different persons to sensitization varies either because of differences in the permeability of the skin or for immunological reasons. In experimental animals, Chase has shown that heredity is an important factor in susceptibility. No such hereditary influence is apparent in clinical practice and contact dermatitis is not related to the familial predisposition to allergies of the asthma and hay fever group. Skin which is already inflamed by burns or pre-existing eczema is more susceptible to sensitization than normal skin.

**Pathogenesis and Morbid Anatomy** Allergic contact dermatitis is an example of the delayed type of allergic reactions. As in other allergies of this group, no antibody is demonstrable in the serum or plasma of the sensitized person. In contact dermatitis of guinea pigs, sensitization is readily transferred to normal animals by injection of lymphoid cells. This phenomenon is believed to reflect the presence of a type of antibody fixed in the cells but is not readily demonstrated in man.

With active sensitizing agents, allergy may be produced in a majority of persons by a single application to the skin. There is no visible reaction to this contact. After an incubation period of ten to twenty days, the entire surface of the skin is sensitized and responds to a second application with dermatitis developing in twenty-four to forty-eight hours. Experimental studies indicate that the causative agent combines with protein of the skin to form a conjugated antigen which passes through the lymph to lymph nodes and other organs of antibody formation. Antibodies which are formed become fixed in the skin and these give rise to the specific reaction on subsequent contact with the hapten-protein conjugate.

The reaction is first manifested by erythema and swelling of the skin due to intercellular and intracellular edema. This progresses to the formation of vesicles and blebs which are easily ruptured by scratching to produce a raw, oozing surface. In this stage, secondary infection, particularly by staphylococci, is common. In chronic cases, the skin may become thickened (lichenified) by scratching. The lesions do not resemble the wheals produced by histamine and their development is not inhibited by antihistaminic drugs. The lesions

contain histamine in far greater concentrations than normal skin but the role of histamine in pathogenesis is not clear

**Symptoms** The lesions usually become apparent within twenty four hours after exposure as redness and edema of the skin progressing to vesicles varying from pin point size to blebs several centimeters in diameter. They are at first limited to the area of contact but in cases of severe sensitivity may be spread to new areas by scratching. The site of the dermatitis depends upon the causative agent and type of contact but the palms soles and scalp are rarely affected. The inflammation of the skin may be accompanied by subcutaneous edema particularly when the face or genitalia are affected. The chief subjective symptom is itching or burning of the involved skin. The general health is rarely affected.

**Differential Diagnosis** Other common eczematous lesions to be differentiated from contact dermatitis are

1 *Atopic dermatitis* the chronic recurrent eczema often beginning in infancy and usually associated with a personal or family history of hay fever or asthma. This characteristically involves the antecubital and popliteal fossae neck and wrists. Vesiculation is rare and lichenification usually marked.

2 *Seborrheic dermatitis* typically involving the scalp postauricular and nasal folds associated with an oily skin and manifested by greasy scales with only mild erythema.

3 *Fungus infections* of the skin particularly involving the skin folds between the toes in the groin and beneath the breasts but also appearing on the trunk as brownish tinea versicolor and as an annular ringworm with central healing.

**Diagnosis of the Causative Agent** The causative agent may usually be suspected from the patient's exposures the time and circumstances of development of the lesions and their distribution. It should be remembered that delicate areas of skin are more susceptible. If the hands are uniformly exposed to the irritant the skin of the dorsum and between the fingers usually reacts more than the palms. Contact dermatitis due to nail polish usually affects the eyelids or neck rarely the hands.

The diagnosis may be established by reproducing the lesion with the patch test in which the suspected agent is applied to normal skin of the back arm or thigh covered with a small adhesive dressing and left in place for two or three days.

Unless the substance is one which is known to be free of primary irritant effects a suitable concentration must be selected by reference to a textbook of dermatology such as that of Sulzberger. To avoid excessive reactions the patch test should not be done during the active stage of acute dermatitis and if severe itching develops before the usual period of observation the patch should be removed promptly and the area washed with soap or a suitable solvent.

**Prognosis and Complications** Complete recovery usually occurs within one to three weeks of the last exposure to the cause. Sensitization must be expected to persist indefinitely. Nephritis has been reported in a few cases as a complication of severe Rhus dermatitis but the etiological relationship is not clearly established.

**Treatment** Most mild cases heal promptly if the causative agent is discovered and removed. Local treatment of more severe cases is selected according to the stage of the lesion. Wet dressings of 5 per cent aluminum acetate for acute oozing lesions and antipruritic lotions such as calamine lotion with phenol for dry lesions. Hydrocortisone ointment 10 or 25 per cent is effective for localized lesions. In severe or spreading dermatitis particularly Rhus dermatitis prednisone or prednisolone 5 to 10 mg. may be given every six to eight hours until the condition is controlled the dose is then tapered off in the course of a week.

When exposure to a known causative agent is unavoidable a protective silicone cream should be applied to the exposed skin before contact and the area scrubbed with soap and water after exposure. Patients who have frequent recurrences of Rhus dermatitis despite reasonable precautions to avoid contact should receive preventive desensitization. This may be carried out either by injections of an extract of the plant or by oral administration. These should not be given during the active stage of the disease. Such measures do not confer complete protection but are useful in conjunction with careful avoidance.

## Urticaria

**Definition** Urticaria or hives is an eruption of the skin characterized by transitory sharply demarcated elevated flat topped wheals usually accompanied by erythema and itching. This rash may occur without other symptoms or as one manifestation of a systemic disease.

**Etiology** Urticaria may be due to a variety of different causes the relative importance of which varies in different localities and different types of practice.

1 Allergy to foods is probably the most frequent cause of acute urticaria but it is relatively less important in chronic cases. Shellfish fish nuts berries and other fruits are common offenders but almost any other food may be the cause. The urticarial reaction to food may be immediate or delayed for twelve hours or more. Skin tests are usually helpful only in the immediate reactions. In severe acute cases gastrointestinal and respiratory manifestations of food allergy may also be present.

2 Allergy to drugs particularly penicillin is a frequent cause. Urticaria due to penicillin frequently is part of a reaction resembling serum sickness with an incubation period of a week or more and lasting another week or two but it may persist for months without further exposure to the drug.

3 Biological medications containing protein may produce urticaria either as an immediate allergic reaction or as delayed serum sickness. In addition to heterologous antiserum insulin and allergen extracts are common offenders in the immediate type of reaction.

4 Allergy to substances touching the skin surface such as silk wool and animal pets is occasionally a cause.

5 Infections of the teeth tonsils sinuses and occasionally of other sites are among the commonest causes of chronic urticaria. Fink and Gay reported that infection was the cause in 30 per cent of 170 chronic cases.

6 Infestation by parasitic worms is an important factor in localities where they are prevalent. In susceptible persons scabies lice mosquitoes bedbugs and other biting insects may produce typical urticaria.

7 Physical allergy to cold light heat or scratching occasionally is the primary cause. More often heat and scratching act as secondary factors in urticaria due to other causes.

8 Stress and emotional factors are major causes of chronic urticaria. In many instances no other etiology is apparent. Some times they are secondary factors in cases primarily due to other causes.

9 Endocrine factors particularly menopause and thyroid insufficiency appear to play a part in some cases—whether primary or secondary is not clear.

In a large proportion of chronic cases variously estimated from 25 (Fink and Gay) to 90 per cent (Hopkins and Kesten) no cause can be clearly established.

The incidence of urticaria is higher in people with a personal or family history of allergies of the familial type but the condition is by no means limited to this group.

**Pathogenesis** The urticarial wheal consists of edema of the skin and results from dilatation of the small vessels and transudation of fluid through the walls of the capillaries in the affected area. The reaction is inhibited by adequate doses of antihistamine drugs and similar lesions may be produced in normal skin by the intracutaneous injection of histamine or histamine liberators suggesting that the local release of histamine is a factor in pathogenesis. There is some evidence that acetylcholine and other intermediaries may also be involved.

In urticaria due to heterologous serum, parasitic worms or insect bites and in the immediate urticarial reactions to foods the release of histamine results from an antigen antibody reaction of the immediate allergic type. Circulating antibodies are usually present and an urticarial wheal may be produced by a skin test with the antigen. In urticaria resulting from infection non protein drugs or delayed allergic reactions to foods such an antibody mechanism is rarely demonstrable but some allergic phenomenon is believed to be involved. The mechanism by which stress produces urticarial wheals has not been clearly established.

**Symptoms** The typical lesions are multiple rounded areas 1 to 4 cm in diameter with a sharply defined edge palpably raised above the surrounding skin surface. Both the wheal and the surrounding skin are erythematous but if the skin is gently stretched the wheal blanches and stands out clearly. The individual lesions usually fade in six to twenty four hours but successive crops may appear in the same or different areas. The palms soles and scalp are rarely affected. When the eyelids lips

contain histamine in far greater concentrations than normal skin but the role of histamine in pathogenesis is not clear

**Symptoms** The lesions usually become apparent within twenty four hours after exposure as redness and edema of the skin progressing to vesicles varying from pin point size to blebs several centimeters in diameter They are at first limited to the area of contact but in cases of severe sensitivity may be spread to new areas by scratching The site of the dermatitis depends upon the causative agent and type of contact but the palms soles and scalp are rarely affected The inflammation of the skin may be accompanied by subcutaneous edema particularly when the face or genitalia are affected The chief subjective symptom is itching or burning of the involved skin The general health is rarely affected

**Differential Diagnosis** Other common eczematous lesions to be differentiated from contact dermatitis are

1 *Atopic dermatitis* the chronic recurrent eczema often beginning in infancy and usually associated with a personal or family history of hay fever or asthma This characteristically involves the antecubital and popliteal fossae neck and wrists Vesiculation is rare and lichenification usually marked

2 *Seborrheic dermatitis* typically involving the scalp postauricular and nasal folds associated with an oily skin and manifested by greasy scales with only mild erythema

3 *Fungus infections* of the skin particularly involving the skin folds between the toes in the groin and beneath the breasts but also appearing on the trunk as brownish tinea versicolor and as an annular ringworm with central healing

**Diagnosis of the Causative Agent** The causative agent may usually be suspected from the patient's exposures the time and circumstances of development of the lesions and their distribution It should be remembered that delicate areas of skin are more susceptible If the hands are uniformly exposed to the irritant the skin of the dorsum and between the fingers usually reacts more than the palms Contact dermatitis due to nail polish usually affects the eyelids or neck rarely the hands

The diagnosis may be established by re-producing the lesion with the patch test in which the suspected agent is applied to normal skin of the back arm or thigh covered with a small adhesive dressing and left in place for two or three days

Unless the substance is one which is known to be free of primary irritant effects a suitable concentration must be selected by reference to a textbook of dermatology such as that of Sulzberger To avoid excessive reactions the patch test should not be done during the active stage of acute dermatitis and if severe itching develops before the usual period of observation the patch should be removed promptly and the area washed with soap or a suitable solvent

**Prognosis and Complications** Complete recovery usually occurs within one to three weeks of the last exposure to the cause Sensitization must be expected to persist indefinitely Nephritis has been reported in a few cases as a complication of severe Rhus dermatitis but the etiological relationship is not clearly established

**Treatment** Most mild cases heal promptly if the causative agent is discovered and removed Local treatment of more severe cases is selected according to the stage of the lesion wet dressings of 5 per cent aluminum acetate for acute oozing lesions and antipruritic lotions such as calamine lotion with phenol for dry lesions Hydrocortisone ointment 10 or 25 per cent is effective for localized lesions In severe or spreading dermatitis particularly Rhus dermatitis prednisone or prednisolone 5 to 10 mg may be given every six to eight hours until the condition is controlled the dose is then tapered off in the course of a week

When exposure to a known causative agent is unavoidable a protective silicone cream should be applied to the exposed skin before contact and the area scrubbed with soap and water after exposure Patients who have frequent recurrences of Rhus dermatitis despite reasonable precautions to avoid contact should receive preventive desensitization This may be carried out either by injections of an extract of the plant or by oral administration These should not be given during the active stage of the disease Such measures do not confer complete protection but are useful in conjunction with careful avoidance

the hereditary form with abdominal pain and vomiting suggestive of an inflammatory or obstructive disease

**Diagnosis** The nature of the lesion is generally apparent from the absence of pain and heat and usually of redness. The presence of simple urticaria elsewhere on the body is also helpful. The underlying structures—for example the teeth and sinuses in lesions of the face—should be carefully examined for evidence of infection. Edema persisting a week or more without remission is rarely angioneurotic edema. In doubtful cases a therapeutic trial with the drugs noted below may be helpful. A distinction between the sporadic and the hereditary forms should be made on the basis of the family history because of the difference in prognosis.

**Prognosis** In the hereditary form frequent recurrences and visceral manifestations are expected. Death from edema of the glottis is the most frequent termination occurring in 21 per cent of 170 cases reviewed by Bullock. In the nonhereditary form this complication is rare. Periodic recurrences over a period of months or years are common unless the cause is found.

**Treatment.** The response of large swellings to symptomatic medication is slow. Epinephrine is indicated particularly if the tongue, pharynx or larynx is involved. One or two doses of 0.5 ml of the 1:1000 aqueous solution may be followed by 1.0 ml of the 1:500 suspension in oil *via* muscularly for a prolonged effect. Relatively large doses of the antihistamine drugs are required. Tripeleminamine (Pyribenzamine) or diphenhydramine (Benadryl) 50 to 100 mg may be given every four hours. In severe or resistant cases prednisone or prednisolone 10 to 15 mg may be given every six hours until the lesion subsides or corticotropin gel 40 to 80 units injected intramuscularly.

When the pharynx or larynx is affected vigorous treatment and close observation are essential. Preparations should be made for a prompt tracheotomy if necessary.

In recurrent or persistent cases an effort should be made to determine the cause and treatment should be directed at its elimination. Infections of the teeth, tonsils, paranasal sinuses or other organs should be treated appropriately. Food allergens suspected as causative factors on the basis of history, observation or skin tests should be avoided. The role of physical or emotional stress should be carefully evaluated.

## Erythemas

The erythemas are a group of skin rashes varying in morphology but all result from reactions of the small blood vessels of the skin. They appear most often as manifestations of sensitization in systemic diseases and as evidences of drug allergy but occasionally without determinable cause. Their classification in the three groups to be described is based on morphology rather than etiology which is quite similar in all. *Urticaria* described in the preceding section and *allergic purpura* described in the section on Hemorrhagic Diseases are closely related phenomena often occurring with the erythemas of this group.

### TOXIC ERYTHEMA

The commonest type of erythema, simple toxic erythema, is a diffuse red rash spread symmetrically over the trunk, thighs and less often the face and arms. This may begin as distinct macules which gradually become confluent (morbilliform rash) or as a diffuse redness which spreads and becomes more intense (scarlatiniform rash). The eruption results from a general dilation of the cutaneous blood vessels of the affected area. In severe cases the vascular reaction may result in small purpuric extravasations of the blood into the skin. The simple erythema blanches on pressure making apparent the purpuric lesions which do not.

Aside from the exanthemata of childhood—measles, rubella and scarlet fever—of which they are a cardinal sign, rashes of this type occur in such other infectious diseases as infectious mononucleosis and rat bite fever. Morphologically similar rashes, both morbilliform and scarlatiniform, are common as manifestations of

or genitalia are involved the lesions are less sharply defined and are accompanied by subcutaneous edema producing the picture of angioneurotic edema. Itching is usually marked and scratching often produces new lesions of elongated form. The total duration of the attack may be a few hours or it may persist for weeks or months.

**Diagnosis** In severe cases one must consider the possibility that the eruption is part of a systemic allergic reaction. Simple urticaria should be distinguished from urticaria pigmentosa, an infiltration of the skin (and often other tissues) by mast cells in which urticarial wheals subside to leave permanently pigmented brownish macules. Differentiation from insect bites is not always easy since allergic persons may react to them with typical urticaria. Usually the bite shows a central puncture and as the wheal fades an itching papule persists for a day or more.

**Treatment** Symptomatic relief of acute cases usually may be obtained by the use of epinephrine 1:1000, 0.5 ml hypodermically repeated after fifteen to thirty minutes if necessary or ephedrine 25 to 50 mg by mouth. Antihistamine drugs such as triphenylamine (Pyribenzamine) 50 to 100 mg, diphenhydramine (Benadryl) 50 to 100 mg or chlorpheniramine (Chlor Trimeton) 8 mg every four to six hours are more suitable in prolonged attacks. If these drugs are not effective prednisone or prednisolone 5 to 10 mg every six to twelve hours may be used for periods of a week or two. Calamine lotion with phenol is helpful as a local application for the relief of itching.

## Angioneurotic Edema

**Definition** Angioneurotic edema, angioedema or giant urticaria is characterized by transitory localized painless swellings of the subcutaneous tissue or submucosa of various parts of the body. It occurs in two

forms: a rare hereditary form in which involvement of the larynx and viscera is frequent and a more common sporadic or nonhereditary type in which visceral lesions are less prominent.

**Etiology** The hereditary form shows a strong familial tendency. The 181 cases reviewed by Dunlop and Lemon representing only 22 families and 33 being reported in one family. In all known marriages in which one parent was affected Phillips and Barrows found that 168 of the offspring developed the disease while 167 did not. This ratio suggests a Mendelian dominant character. However in 37 marriages in which a grandparent but neither parent had the disease 17 of 111 offspring were affected indicating that a more complex genetic mechanism is involved. There is no definite evidence that allergy, infection and stress are significant etiological factors in this hereditary type of edema.

The nonhereditary or sporadic type is essentially a giant form of urticaria often occurring with simple urticaria and due to similar causes, notably allergy to foods or drugs, infection and emotional stress. This type is more common in people with a personal or family history of allergy but also occurs in others.

**Pathogenesis** The development of angioedema like that of urticaria results from dilatation of the small blood vessels and transudation of fluid through the capillaries but the lesion of angioedema is primarily in the subcutaneous tissue. The overlying skin may or may not be affected. The vascular change is believed to be due to local release of histamine.

**Symptoms** The lesion is most often single but may be multiple. It consists of a tense nonpitting rounded swelling a few centimeters or more in diameter. The edema is localized but lacks the sharply defined raised border typical of urticaria. The overlying skin is usually normal in color and temperature but may be slightly reddened. There is no pain, itching is rare and the chief sensation is one of distention. The individual lesions persist for one to three days and leave no residual changes. Successive attacks may involve the same or different locations. The face, hands, feet and genitalia are the skin areas most often affected. Involvement of the lips, tongue and pharynx is not unusual. In the hereditary form laryngeal edema is a frequent cause of death but this lesion rarely occurs in the sporadic type. Involvement of the gastrointestinal system is also common in

allergy to a wide variety of different drugs notably the sulfonamides thiouracil arsenicals and para aminosalicylic acid These drug rashes are often but not always accompanied by drug fever of  $101^{\circ}$  to  $104^{\circ}$  F If the patient is taking the drug for the first time these two manifestations of drug allergy usually appear simultaneously in the second week of use but in patients previously sensitized they may be apparent in a few hours In general both rash and fever subside promptly when the causative drug is discontinued

### ERYTHEMA MULTIFORME

Erythema multiforme is an acute eruption of the skin manifested by various lesions which may include macules papules vesicles bullae urticarial wheals and purpura present simultaneously or at different stages of the eruption The distribution is symmetrical involving the extremities particularly the dorsal surfaces of the hands and feet the face and trunk are less often affected The mucosae of the mouth are frequently involved the penis and vagina occasionally

The onset is abrupt and often accompanied by fever The initial lesions are usually intensely red macules or urticarial wheals In the course of a day or two these lesions may show central clearing to produce ring forms or characteristic target lesions composed of two concentric rings In more severe cases the initial lesions progress rapidly to bullous and purpuric forms Coalescence of individual rounded lesions gives rise to bizarre shapes and sizes The appearance of successive crops of lesions leads to the simultaneous presence of many stages Itching is usually not severe The attack tends to subside completely in a period of a week to a month but recurrences are common

This type of rash may be associated with infections particularly rheumatic fever It is also one of the skin manifestations of serum sickness and of similar reactions to penicillin Other drugs known to produce allergic rashes of this type include sulfonamides phenylbutazone arsenicals and antipyrine Some cases of erythema multiforme are associated with malignant tumors an initial attack in middle age or later should suggest that possibility A considerable proportion of the cases in children recur periodically without known cause

The only effective treatment is with drugs of the cortisone group—for example prednisone or prednisolone 10 to 15 mg

every six hours until the condition is controlled

**Stevens Johnson Syndrome** A severe type of bullous erythema is ectodermosis erosiva pluriorificialis commonly known as Stevens Johnson syndrome which affects children and young adults The onset is characterized by high fever malaise and ulcerative lesions of the conjunctivae mouth genitalia and anus followed in a day or two by a generalized bullous eruption The etiology of this type is unknown Recovery may be followed by permanent damage to the eyes It is not infrequently fatal Cortisone derivatives are the most effective medications Tetracycline or other antimicrobial drugs may be used to control secondary infections

### ERYTHEMA NODOSUM

The rash of erythema nodosum consists of a relatively few tender red or purplish nodules usually 2 to 5 cm in diameter appearing chiefly over the shins but occasionally on the thighs and forearms These subside without ulceration over a period of two weeks but successive crops may appear so that the total duration may be four to six weeks There is no itching but pain is frequent The onset is characterized by fever and general malaise Histological sections of the lesions show dilatation of the vessels and dense perivascular infiltration of the subcutaneous tissue by wandering cells with some extravasation of red cells This type of rash usually results from allergic reactions to various infective agents and certain drugs It occurs most frequently as a sequela of hemolytic streptococcus tonsillitis or pharyngitis but may also be associated with rheumatic fever tuberculosis coccidioidomycosis ulcerative colitis lymphopathia venereum sarcoidosis and other systemic diseases The drugs most frequently causing this type of reaction are the sulfonamides thiouracil bromides and iodides

Because of the possible implications of serious systemic diseases careful diagnostic studies to establish the cause are warranted in all cases Therapy is directed primarily at the underlying disease Symptomatic treatment of the eruption is only occasionally needed Aspirin is helpful for pain The most effective medications are cortisone derivatives but these should be used only if the possibility of tuberculosis has been excluded

# Diseases of Connective Tissue

## Introduction

The collagen or connective tissue diseases represent a group of clinical syndromes which are considered together because they have certain histological features in common such as widespread inflammatory damage in the connective tissue and the production of fibrinoid change in the ground substance. Each of these diseases presents a distinct clinical pattern but they are in general characterized by constitutional manifestations as well as local lesions in joints, blood vessels, heart, skin, muscle, and the supporting reticulum of the internal organs. The clinical features are largely determined by the distribution of these lesions and the rate of development of the tissue changes. The symptomatic response of certain manifestations of these diseases to adrenocortical steroids stimulated the belief that there might be a common thread running through their etiological background. Increasing experience, however, suggests that the pituitary-adrenocortical system has only a regulatory function, damping down reactions to injury and disease but having no basic relation to the fundamental factors concerned in pathogenesis.

Before discussion of the various diseases in this group it would be well to summarize the current knowledge of the anatomy, physiology, and pathological physiology of the connective tissue system. The supporting system or connective tissue system is the extracellular framework of the body which is composed of structural elements (the fibers) which are largely protein in composition set in a nonstructural matrix (the ground substance) largely polysaccharide in nature. For the performance of its supporting and lubricating functions, the system combines a maximal

degree of physical stability with a minimal metabolic activity.

The principal cellular element is the fibroblast which, along with its close relatives the osteoblast and the chondroblast, seems to be responsible for the elaboration of most of the other endogenous elements and for their maintenance. Other cellular elements include the mast cell concerned in the formation of heparin and the wandering cells or macrophages. In fresh granulation tissue the cells are relatively numerous and the intercellular material is scanty and largely mucoid in nature. In well differentiated adult tissues the cells are relatively few, inactive, and tend to be separated from each other by large amounts of intercellular material.

The fibrous constituents of connective tissue comprise two main groups: collagenous and elastic. Collagen is a fibrous protein occurring in wavy, birefringent bundles of unbranched, acidophilic fibrils cemented together in a polysaccharide matrix and characterized chemically by low content of aromatic amino acids and high content of proline, hydroxyproline, and glycine. It represents approximately 30 per cent of the total body protein. Nageotte and others demonstrated that certain collagens, such as the rat tail tendon, could be dissolved in dilute acids to form clear, viscous solutions. Fibers could be reprecipitated from such solutions by the addition of sodium chloride. This phenomenon has been interpreted as a simplified model for the biological fibrogenesis of collagen. The structural specificity of the fibers formed resides in the dissolved collagen structures precipitated from the solution. These and other studies have led to the concept of a fundamental collagen building block termed tropocollagen, which is manufactured and released in soluble form by the

cell. After extrusion into the extracellular environment ionic and other conditions favor its precipitation and orderly lineal aggregation into the collagen fibril. The argyrophilic reticular fibers believed to be precursors of collagen fibrils are arranged in parallel wavy bundles. Such fibers form the delicate supporting network of organs like the spleen. They are also found in developing connective tissue and are the finest of the three types. Though distinguishable from collagenous fibers by their staining reaction, they are made up of the same macromolecular fibrils; the reticular fibers simply representing smaller aggregations of fibrils. Elastic fibers are characteristically branched and smooth. They are found in large numbers only in special areas, such as ligaments and the walls of arteries.

Histologically the mucoid forms the ground substance which lies between the connective tissue fibers and fibrils. It may show metachromasia with toluidine blue and may stain deeply with the McManus technique. Chemically it is composed of mucopolysaccharides which are highly polymerized long chain forms of a basic disaccharide composed of equimolecular parts of glucuronic acid and an amino sugar. These mucopolysaccharides are divided into two groups on the basis of the presence or absence of sulfate. Sulfate free hyaluronic acids are concentrated in ground substance between the formed elements and appear to function mainly as lubricants and shock absorbers. Sulfated polysaccharides form cement substance within collagen and cartilage and also function as polyelectrolytes in the binding of cations in a manner comparable to that of the synthetic ion exchange resins. In the tissues the polysaccharides are normally highly polymerized and the increased spread of fluid which follows the introduction of hyaluronidase containing extracts has been attributed to depolymerization of the tissue polysaccharide. The capacity of polysaccharides to form viscous lubricating fluids or a stabilizing tissue matrix depends upon their degree of polymerization rather than upon the total content. Polymerization is greatest at the site of formation of basement membrane. Where toughness is a characteristic, sulfate mucopolysaccharide is present acting as a cementing material between the collagen bundles. Where lubrication is the prime need as in joint spaces and the vitreous of the eye, hyaluronic acid is found.

Physiologically the complex functions in

connective tissue depend for their integrity not only on fibroblastic activity but also upon a satisfactory supply of building material from blood and important regulators including enzymes, vitamins and hormones. The hyaluronidases, antihyaluronidases, collagenases and heparin are examples of enzymes and enzyme inhibitors playing an important role among the vitamins and hormones are ascorbic acid, testosterone, estrogen and adrenocortical steroids. All the factors and pathways have not been delineated but the system is clearly a "connecting substance" forming a barrier which must be crossed by water, electrolytes, nutrients and metabolites being exchanged between blood and the parenchymal cells in all areas.

There are three principal reactions of connective tissue to injury: fibrinoid necrosis, fibrillary augmentation leading to sclerosis, and cellular invasion and proliferation. Following trauma or inflammation, a tissue substance is released which causes an increase in capillary permeability with influx of polymorphonuclear leukocytes, lymphocytes and monocytes. At the area of increased permeability there is local adhesion of leukocytes to the capillary wall. In the development of sclerosis or fibroplasia, new fibroblasts soon appear and shortly afterwards ground substance. As reticular and collagenous fibers develop, new blood vessels grow out from capillary buds on pre-existing vessels.

Cortisone and other similar adrenal steroids decelerate and thereby inhibit fibroplasia. Desoxycorticosterone acetate and growth hormones accelerate and augment it. The spreading reaction induced by hyaluronidase is inhibited by ACTH. Cortisone may also modify the invasive tendency of macrophages through an effect on capillary permeability and margination of the white cells.

In the absence of vitamin C, fibroblasts migrate widely, multiply rapidly, assume the morphology of embryonic connective tissue and produce a liquid material instead of normal matrix. No new collagen is laid down and reticulum does not appear. Thus the fibroblast matures but fails to produce the normal extracellular components of connective tissue.

With advancing age, the mucoid content of most connective tissues decreases while the collagenous component increases and tends to be organized into a coarser fiber pattern. These tissues become less elastic and resilient and as a result less able to resist mechanical forces. This is one rea-

son why our limbs become stiff and readily damaged by trauma as aging occurs

Fibrinoid degeneration along with the accompanying inflammatory reaction has come to be the accepted histological hall mark of the collagen diseases. In the fibrinoid lesion connective tissue cells are either few or absent and the regular fiber pattern of normal connective tissue is replaced by swollen indistinct bundles or clumps of amorphous material which stain more intensely with eosin than the surrounding connective tissue. In sections treated by the McManus technique the fibrinoid areas stain strongly with the magenta color considered to indicate the presence of polysaccharides. Fibrinoid differs markedly from normal collagen and the opinion has been expressed that in its formation the collagen polysaccharide complex of normal connective tissue is destroyed the collagen being removed but the polysaccharides remaining in an unusually insoluble form.

As our knowledge of the connective tissue system and its normal function in creases and the various clinical and pathological syndromes are more clearly delineated investigative developments in regard to etiology and pathogenesis will emerge on which sound and specific measures for prevention and treatment can be based. The clinician who studies these problems should develop the habit of regarding the connective tissue system as a whole if the diverse body of information which is accumulating is to be efficiently and usefully synthesized.

## Systemic Lupus Erythematosus

**Introduction and Definition** Systemic lupus erythematosus (SLE) is a disease with varied clinical manifestations associated with lesions of connective tissue in the vascular system the dermis and the

serous and synovial membranes. There is usually a prolonged clinical course characterized by exacerbations and remissions over a period of years. The development of the typical erythematous butterfly facial lesion facilitates diagnosis but is often not present. Frequently there are marked constitutional symptoms and the multitude of visceral manifestations may present in a complex pattern making diagnosis difficult.

**Classification** into acute subacute and chronic categories other than to describe the clinical course of dermal lesions serves no purpose. The activity of the disease varies and the acuteness of the illness merely denotes the severity at any one time. The term SLE refers to the generalized form of the disease and the terms discoid and disseminated are used to describe the dermal lesions.

**Incidence** With the recognition that SLE is usually a chronic relapsing process with protean manifestations it is clear that it is relatively common particularly among young females. Several observers in general hospitals have collected 100 to 200 cases since the advent of the LE cell test as a diagnostic aid. However until a specific universally positive diagnostic test is developed the true incidence will remain unknown.

**Etiology** Infectious agents both viral and bacterial have been implicated but on no solid evidence. The predominance in females has led to speculation about endocrinological factors. Some constitutional predisposition of unknown character seems possible. Because of the multitude of protein abnormalities observed this disease might be due to an autoimmune mechanism.

**Pathology and Pathogenesis** There may be a paucity of anatomical findings even though the patient has an acute fulminating disease. Microscopically the lesions in the connective tissue include (1) fibrinoid change (see Introduction) (2) sclerosis of collagen as manifested by periarterial fibrosis in the spleen (3) the development of hematoxylin bodies and (4) cellular infiltration. The so called hematoxylin bodies are purple staining globules which arise from alteration in the nuclei of cells of mesenchymal origin. They have been noted in the heart lymph nodes kidney lung and spleen. The composition of the nucleoprotein of these bodies differs from that of normal nuclear material in the absence of histone some loss of deoxyribonucleic acid (DNA) and in the seemingly increased amount of unusual protein ma-

terial The most recent evidence does not support the concept that there is depolymerization of DNA

**Clinical Manifestations** At onset a single organ system may be involved or dysfunction may be noted in several systems Initially the skin and joints are most frequently affected but the disease may begin with a pneumonitis thrombocytopenic purpura or a psychotic episode suggesting a local rather than a generalized process The initial symptoms may be vague making it difficult to date the onset The patient may state that she "has always been sensitive to the sun" or has had recurrent mild arthralgia for many years The majority of patients have constitutional difficulties with fever

**Joint Involvement** Most commonly involved are the hands wrists elbows shoulders knees and ankles Characteristically there is a disproportion between the severity of the discomfort and the objective evidence of arthritis Joint pains tend to appear episodically and are often migratory In some patients contractures muscular atrophy and joint deformity may be disabling Tenderness in muscles and periarthritic tissues frequently accompanies the arthritis The muscle involvement may be so extensive as to suggest dermatomyositis or a primary myopathy

**Mucocutaneous Manifestations** The typical "butterfly" eruption appears in less than half the patients and in a significant number cutaneous lesions do not develop Symmetrically distributed erythematous lesions may be seen on the ears neck back chest shoulders arms hands and feet The other characteristic but rare dermal lesion is purplish erythema often followed by ulceration and scarring about the nail beds Urticaria and angioneurotic edema are frequent The pigmentation and thickening of the skin may resemble scleroderma Subcutaneous nodules have been described Vascularization of the cutaneous lesions may occur with the development of telangiectases The mucosal lesions are erythematous petechial or ulcerative

The dermal lesions in chronic discoid lupus consist of erythematous plaques of varying sizes with scaling and follicular plugging followed in the healing stages by atrophy and scarring with either hyperpigmentation or areas of vitiligo In the localized form the lesions are confined to the face ears and scalp while in the generalized form also referred to as the chronic disseminated form lesions appear elsewhere on the body The patient with the

chronic discoid form may suddenly develop acute systemic manifestations or such manifestations may be present in variable and less fulminating form over many years

**Renal Involvement** Kidney involvement is present in 75 per cent of patients dying of SLE Serial biopsies reveal that the earliest renal lesion is a localized membranous glomerulitis With progression there is the appearance or increase of fibrinoid material in the basement membrane adhesions develop between the tuft and Bowman's capsule and in some cases local areas of necrosis are found Tubular degeneration is usually evident In the end the kidney may be indistinguishable from that of early chronic glomerulonephritis of the common type

The renal disease may run a fulminating course (pseudonephrotic syndrome) in which glomeruli are severely damaged from the onset with death from kidney failure within a few weeks or months The clinical picture is that of nephrosis with the exception that the serum cholesterol is low

On the other hand it may develop slowly in a patient ill for a long period with other symptoms In the early stage the urine may contain protein leukocytes in clumps and leukocyte casts leading to an erroneous diagnosis of pyelonephritis As the lesion progresses erythrocytes and granular casts appear in the urine of most patients and epithelial cells fatty casts and oval fat bodies in the urine of some patients The clinical manifestations include nocturia polyuria and thirst Many patients pass through an edematous stage associated with hypoalbuminemia hypercholesterolemia and massive proteinuria Histologically membranous and proliferative changes are seen in the glomerular tufts and tubular degeneration is usually evident When this nephrotic syndrome appears other clinical manifestations may be quiescent and the diagnosis of SLE overlooked The edematous stage may persist for months gradually progressing into one of chronic renal insufficiency Secondary infection of the genitourinary tract is common

**Cardiovascular Manifestations** Over half the patients have involvement of the pericardium endocardium or myocardium Pericarditis is usually manifested by precordial discomfort or a friction rub significant degrees of effusion being unusual In a disease characterized by fever and anemia the interpretation of systolic murmurs is difficult and the correlation of clinical and pathological evidence of the

verrucous endocarditis of Libman Sacks is not good Occasionally a superimposed bacterial endocarditis develops usually on the mitral valve where the verrucous lesions are most common At times lesions in the myocardium result in heart failure with tachycardia gallop rhythm and cardiac enlargement Raynaud's phenomenon is often an early manifestation

**Pleural and Pulmonary Involvement** Pleurisy is one of the hallmarks of SLE An anaphylactoid pneumonitis is frequently present and may resemble atypical pneumonia of viral origin There may be progressive tachypnea dyspnea and cyanosis Scattered fine or coarse rales usually at the lung bases may be the only findings Radiological study may reveal elevation and fixation of one or both diaphragms with areas of platelike atelectasis above Bacterial infections of the lungs are common

**Nervous System Manifestations** Over one fourth of these patients show evidence of mental and neurological dysfunction The mental reactions are diverse and include anxiety memory defects hallucinations and obsessional and paranoid reactions Convulsions are frequent Other neurological findings described are diplopia nystagmus hemiplegia and polyneuritis The spinal fluid may show increased cells and protein sometimes accompanied by signs of meningitis Cotton wool retinal exudates are frequently observed In the absence of hypertension and diabetes these cytooid bodies in the nerve fiber layer of the retina are a helpful point in diagnosis

**Gastrointestinal Manifestations** These include anorexia nausea vomiting and abdominal pain which may be so acute as to simulate conditions requiring surgical intervention Dysphagia is due to arteritic lesions in the esophagus Pancreatitis has occasionally been prominent Diarrhea with bloody stools and abdominal cramps may be present and severe paralytic ileus has been noted

**Liver Spleen and Lymph Nodes** Although hepatomegaly is often found the usual cause is fatty infiltration and the lesions of lupus are seldom present The spleen is palpable in 15 to 20 per cent of cases Regional or generalized lymph node enlargement occurs in over half the patients and may be so impressive that a diagnosis of a primary lymphatic disease is made

**Hematological Abnormalities** Leukopenia is common and is due to a predominant decrease in mononuclear cells with a high proportion of neutrophils Eosinophils are often

reduced in number Leukocytosis is unusual unless the process is fulminating but may result from superimposed infection or steroid therapy

Purpura is usually the result of a vascular defect Occasionally a hemorrhagic disorder similar to idiopathic thrombocytopenic purpura may develop preceding by months or years other obvious manifestations of SLE ACTH or adrenocortical steroids usually produce a transient rise in platelets Splenectomy has been uniformly effective in the writer's experience and in most instances there has been no recurrence

In the majority of cases an anemia due to retarded erythropoiesis develops If there is renal insufficiency or a superimposed infection it may become severe A few patients have an acute hemolytic anemia which has the character of an acquired autoimmune disorder with reticulocytosis jaundice and a positive Coombs test Splenectomy is of no benefit but adrenal steroids are effective in controlling the hemolysis

Hypergammaglobulinemia is demonstrable in most cases and other protein abnormalities including increase in fibrinogen autoagglutination of erythrocytes elevation of the sedimentation rate positive flocculation tests and biological false positive tests for syphilis are frequently encountered Cryoglobulins have been noted as well as the occasional appearance of a circulating anticoagulant associated with prolongation of clotting and prothrombin times

**LE Cell Phenomenon** A protein factor contained in the plasma of the majority of cases can induce formation of LE cells in leukocytes obtained from blood marrow or other sources

The typical LE cell consists of a neutrophilic granulocyte distended by a large purple red homogeneous globular inclusion body which compresses the nucleus against the cell membrane leaving only a thin rim of cytoplasm The inclusion body is derived from nuclear material released from other leukocytes and altered under the influence of the plasma factor The LE cell is then formed when this altered nuclear material is ingested by a phagocytic cell In positive LE cell preparations there are frequently extracellular masses of globular material identical in appearance and staining reaction with the LE cell inclusion This extracellular material is often surrounded by polymorphonuclear leukocytes forming rosettes

Heparin is the preferable anticoagulant because there is less distortion of the leukocytes. Coagulation and rotation with glass beads result in injury to leukocytes thus presenting more nuclear material for interaction with the LE factor in serum.

Recent studies have shown that when nuclear material is incubated with positive LE serum and then the nuclei removed by centrifugation the serum loses its ability to induce LE cell formation. If all the DNA is removed from the nuclear material by treatment with DNAase no LE factor is absorbed. Absorption of LE factor was also prevented by prior treatment with protamine thought to bind the phosphate group of DNA and with Atabrine an agent having some therapeutic action in this disease. When slides containing LE cells are reacted with fluorescent rabbit antiserum to normal human gamma globulin nuclei undergoing change preliminary to phagocytosis during LE cell formation and the inclusion bodies of LE cells fluoresce brilliantly indicating localization of the gamma globulin presumably the LE factor on the affected nuclei. These findings suggest that the LE serum factor has an affinity for nuclear nucleoprotein and that DNA is involved in the bond. The question may be raised as to whether the LE factor could be an autoantibody to nucleoprotein or deoxyribonucleic acid. There is no regular correlation between the severity of the disease and the number of LE cells produced. Some patients with unequivocal SLE in an active stage cannot be demonstrated to form LE cells.

Leukocytes which have engulfed lymphocyte nuclei have been mistaken for LE cells. False positive results have been reported in cases of rheumatoid arthritis, hemolytic anemia and glomerulonephritis but it seems probable that the patient's disorder was a manifestation of SLE. Patients may develop a lupus like syndrome after prolonged therapy with hydralazine and in some of these cases LE cells have been demonstrable. The reported rare occurrence of LE cells with other drug reactions particularly penicillin hypersensitivity remains to be clarified.

LE cells have been found occasionally in patients with a syndrome referred to as active chronic hepatitis the features of which are prolonged jaundice, occurrence in young females, pyrexial episodes, hepatomegaly and pronounced splenomegaly, occasional ascites and a raised gamma globulin level. Histologically there are fibrosis and nodular regeneration with

striking infiltration of lymphocytes, plasma cells and histiocytes. A butterfly rash has been noted and also hemolytic anemia. It is postulated that viral and possibly nutritional damage to the liver can lead to a situation in which liver-cell components become antigenic and may stimulate the production of antibodies which react damagingly with liver and other body tissues leading to perpetuation of the hepatitis and occasionally to the initiation of the clinical picture of lupus erythematosus.

**Course of SLE.** The course of SLE is characterized by periods of exacerbation and remission during which a number of organ systems may be involved in an episodic manner. The disease may extend over many years or may end in a fulminant manner in a few weeks or months. A protracted course during which the various manifestations become evident in a confusing and complicated manner is the usual picture. Spontaneous remissions are common and may occur on more than one occasion lasting for months or even years. The development of an infection or the administration of a drug may serve as the trigger for enhancement of activity.

Before the antibiotic era patients most frequently died of a complicating infection, particularly of the respiratory or urinary tract but now progressive renal involvement or central nervous system disturbances due to the disease itself are the most ominous developments.

There is a sustained false positive serological test for syphilis (BFP) in approximately 20 per cent of patients with SLE. Pertinent to the clinical course of SLE is the etiological background of the chronic BFP phenomenon. One hundred forty eight patients all essentially well when shown to have this phenomenon have been followed from one to twenty years. Approximately 7 per cent have subsequently developed verified SLE, 5 per cent typical rheumatoid arthritis and 30 per cent one or more clinical episodes compatible with a widely disseminated connective tissue disorder. In another 29 per cent still clinically well other serum protein abnormalities have been discovered.

Considering the cases of SLE which can be clinically recognized and estimating survival from time of diagnosis, one may expect a mortality of about 10 per cent per year. Survival may be much longer if one estimates duration from retrospective determination of the first manifestation of the disease.

**Diagnosis.** The clinical diagnosis of SLE

verrucous endocarditis of Libman Sacks is not good Occasionally a superimposed bacterial endocarditis develops usually on the mitral valve where the verrucous lesions are most common At times lesions in the myocardium result in heart failure with tachycardia gallop rhythm and cardiac enlargement Raynaud phenomenon is often an early manifestation

**Pleural and Pulmonary Involvement** Pleurisy is one of the hallmarks of SLE An "anaphylactoid pneumonitis is frequently present and may resemble atypical pneumonia of viral origin There may be progressive tachypnea dyspnea and cyanosis Scattered fine or coarse rales usually at the lung bases may be the only findings Radiological study may reveal elevation and fixation of one or both diaphragms with areas of platelike atelectasis above Bacterial infections of the lungs are common

**Nervous System Manifestations** Over one fourth of these patients show evidence of mental and neurological dysfunction The mental reactions are diverse and include anxiety memory defects hallucinations and obsessional and paranoid reactions Convulsions are frequent Other neurological findings described are diplopia nystagmus hemiplegia and polyneuritis The spinal fluid may show increased cells and protein sometimes accompanied by signs of meningitis Cotton wool retinal exudates are frequently observed In the absence of hypertension and diabetes these cytoid bodies in the nerve fiber layer of the retina are a helpful point in diagnosis

**Gastrointestinal Manifestations** These include anorexia nausea vomiting and abdominal pain which may be so acute as to simulate conditions requiring surgical intervention Dysphagia is due to arteritic lesions in the esophagus Pancreatitis has occasionally been prominent Diarrhea with bloody stools and abdominal cramps may be present and severe paralytic ileus has been noted

**Liver Spleen and Lymph Nodes** Although hepatomegaly is often found the usual cause is fatty infiltration and the lesions of lupus are seldom present The spleen is palpable in 15 to 20 per cent of cases Regional or generalized lymph node enlargement occurs in over half the patients and may be so impressive that a diagnosis of a primary lymphatic disease is made

**Hematological Abnormalities** Leukopenia is common and is due to a predominant decrease in mononuclear cells with a high proportion of neutrophils Eosinophils are often

reduced in number Leukocytosis is unusual unless the process is fulminating but may result from superimposed infection or steroid therapy

Purpura is usually the result of a vascular defect Occasionally a hemorrhagic disorder similar to idiopathic thrombocytopenic purpura may develop preceding by months or years other obvious manifestations of SLE ACTH or adrenocortical steroids usually produce a transient rise in platelets Splenectomy has been uniformly effective in the writer's experience and in most instances there has been no recurrence

In the majority of cases an anemia due to retarded erythropoiesis develops If there is renal insufficiency or a superimposed infection it may become severe A few patients have an acute hemolytic anemia which has the character of an acquired autoimmune disorder with reticulocytosis jaundice and a positive Coombs test Splenectomy is of no benefit but adrenal steroids are effective in controlling the hemolysis

Hypergammaglobulinemia is demonstrable in most cases and other protein abnormalities including increase in fibrinogen autoagglutination of erythrocytes elevation of the sedimentation rate positive flocculation tests and biological false positive tests for syphilis are frequently encountered Cryoglobulins have been noted as well as the occasional appearance of a circulating anticoagulant associated with prolongation of clotting and prothrombin times

**LE Cell Phenomenon** A protein factor contained in the plasma of the majority of cases can induce formation of LE cells in leukocytes obtained from blood marrow or other sources

The typical LE cell consists of a neutrophilic granulocyte distended by a large purple red homogenous globular inclusion body which compresses the nucleus against the cell membrane leaving only a thin rim of cytoplasm The inclusion body is derived from nuclear material released from other leukocytes and altered under the influence of the plasma factor The LE cell is then formed when this altered nuclear material is ingested by a phagocytic cell In positive LE cell preparations there are frequently extracellular masses of globular material identical in appearance and staining reaction with the LE cell inclusion This extracellular material is often surrounded by polymorphonuclear leukocytes forming "rosettes"

regard in patients with cardiovascular or renal involvement. If there is any evidence of tuberculosis, adequate antimicrobial therapy should be given during steroid administration.

The steroid of choice is administered in the amount necessary to control the active manifestations of the disease and in some patients the manifestations of Cushing's syndrome will result.

A majority of patients will be benefited dramatically within a few days. General well-being is enhanced, appetite increases, pyrexia is suppressed, regression of active cutaneous lesions takes place, joint manifestations subside, cardiac symptoms decrease unless accompanied by renal involvement, and there is usually subjective improvement in those with pulmonary involvement.

The initial dosage is maintained for several days. If there is no beneficial response, the dose is then raised in a stepwise manner until a favorable effect is obtained or indications of overdosage appear. The optimum amount for improvement is then maintained until the major signs and symptoms have been suppressed to maximum degree. The dose is then reduced in a stepwise manner, for example 25 to 50 mg of cortisone every two to four days. If there is a recrudescence, the dose is again raised. On the other hand, if there is no exacerbation or if symptoms return to only a minor degree, reduction of steroid may proceed. The decision to begin lowering the dose of steroid is based more on the status of the clinical manifestations of the disease than on any laboratory observations. These hormones merely reduce the inflammatory response and do not affect the fundamental cause of the lesions. When the underlying process improves spontaneously, little or no steroid therapy will be necessary to keep the patient in a state of clinical remission.

When the nephrotic syndrome is present, high protein feeding (15 gm/kg/24 hours) and dietary sodium restriction are indicated. When chronic renal failure is present, the dietary protein is restricted to about 40 gm daily. The patient should be instructed to maintain an adequate fluid intake (2500 to 3000 ml daily). Frequent electrolyte determinations enable one to anticipate and treat serious electrolyte imbalance. The general measures are those used in the management of any patient with chronic nephritis and renal insufficiency. No evidence of regression of structural damage has been found to take place during

steroid therapy (renal biopsy studies) and neither is there evidence that these hormones cause progression of the renal lesions. The patient should be treated with steroids at the earliest sign of renal involvement in the hope of retarding progress or preventing irreversible damage. If after steroid administration there is no improvement in the face of serious renal involvement, nitrogen mustard may be tried in a single dose of 20 mg intravenously (adults).

## Dermatomyositis

(Neuromyositis, Polymyositis, Dermatomyosomyositis, Poliodermatomyositis)

**Definition.** There has been no more satisfactory definition of this disease in its classic form than that proposed by Steiner.

An acute, subacute, or chronic disease of unknown origin characterized by a gradual onset with vague and indefinite prodromata followed by edema, dermatitis, and multiple muscle inflammation. The common denominator of this syndrome is the acute or subacute degeneration of skeletal muscles, and the descriptive terms are utilized to indicate the combination of tissues involved in the individual case.

**Etiology and Incidence.** The etiology is unknown. Many cases have had their onset during or after some type of infection but no causative relationship has been established. Other observers have suggested an allergic background, a disturbance in vitamin E metabolism, or an endocrine factor, but no conclusions can be reached from the information available. In about 18 per cent

can be made consistently only when the observer appreciates that this syndrome frequently has a protracted course unfolding in an episodic manner over many years. When confronted by what appears to be a disorder of a single organ system such as arthritis a hemolytic anemia an obscure nephritis or an unexplained psychotic reaction the observer must search the background for past illnesses which might be related. SLE may appear with a confusing array of manifestations resulting from multi system involvement in which it is difficult to detect any obvious continuity. It is particularly important to look for the variety of plasma protein serological and hematological abnormalities which have been pointed out. The diagnosis can often be substantiated by demonstration of the LE cell phenomenon or the proper interpretation of biopsy material obtained from the skin subcutaneous tissues muscle lymph node or kidney.

**Hydralazine Syndrome** Hydralazine is used in the treatment of hypertension. In 7 to 10 per cent of patients who receive an average daily dose of 600 mg or more over periods averaging twelve months a syndrome develops which may simulate SLE. It usually appears as the diastolic pressure falls to normal and is often precipitated by an intercurrent infection. Initially there may be chills and migratory joint and muscle pains. If the drug is continued a febrile phase ensues manifested by fever pleural pericardial and joint effusions skin sensitivity to light erythematous eruptions lymphadenopathy and splenomegaly. There may be decreased serum albumin concentration increase in alpha and gamma globulins increased erythrocyte sedimentation rate transient false positive tests for syphilis anemia leukopenia and in some instances the development of the LE cell phenomenon. Renal abnormalities are unusual. The syndrome is predominant in males and is reversible when the drug is stopped. The relationship to total dose and duration of administration does not suggest a sensitization phenomenon.

**Treatment** The control of pain by use of suitable analgesics the treatment of complicating infections with appropriate antibiotics transfusions for the correction of anemia and digitalis and sodium restriction in the cases with heart failure are examples of numerous standard measures which are utilized when indicated. Limitation of activity during the active phase of the disease is desirable. Undue exposure to the sun is unwise in view of the frequent

presence of photosensitivity and no drugs should be administered unless there is an urgent therapeutic indication since fulminating manifestations may be precipitated. When fever and joint symptoms are prominent salicylate administration may be beneficial and occasionally the results are dramatic.

Certain antimalarial drugs particularly Atabrine and chloroquine are used to treat milder forms of the disease and those patients who have been on high doses of adrenocortical steroids for prolonged periods and in whom it is not possible to reduce the maintenance dose. After a period of weeks on these drugs a lichenoid dermatitis may develop or the drug may have to be discontinued because of convulsions a psychotic reaction or gastrointestinal symptoms. The most striking result is improvement in the arthritic and cutaneous lesions. The suggested dose of Atabrine is 100 mg three times daily after meals. If there is no improvement in one week it may be gradually increased to 600 mg daily. Larger doses are usually no more effective and the incidence of toxic effects increases. Chloroquine is now more often used than Atabrine and appears to be less toxic. The effective dose appears to be about 500 mg to 750 mg daily. This is used for one to four weeks until a clear response is obtained when the dose is reduced to 500 to 250 mg and maintained. In 50 to 75 per cent of patients there is either clearing of the dermatitis or definite improvement. The recurrence rate after stopping the drug is high. In view of the reported cases of severe bone marrow damage these drugs should be used with caution.

The active manifestations of SLE can be most adequately and promptly controlled by adrenocortical steroid therapy. In the moderately or seriously ill patient the starting dose may be cortisone 300 mg hydrocortisone 200 to 250 mg or prednisone 40 to 60 mg. There has been little difficulty with permanent adrenal suppression from long term use of these steroids if they are tapered gradually and their administration is not terminated rapidly without prior administration of ACTH. With long term use of any of these steroids it is necessary to employ anticholinergic drugs antacids and frequent feedings because of the tendency to peptic ulceration. The status of carbohydrate metabolism should be followed closely. Sodium restriction and oral potassium administration should be employed when moderate or large doses of steroid are given. Special care must be taken in this

erythematosus there may be a relation between the appearance or intensity of the cutaneous manifestations and exposure to sunlight. In some cases there is extensive calcification in the subcutaneous tissues.

An intermittent fever may be present. Malaise, anorexia and loss of weight are common. Involvement of the joints is rarely seen although pain in periarticular areas often results from lesions of the soft tissues and tendons. Alopecia of varying degree may develop and hypertrichosis is sometimes noted. Occasionally present are lymphadenopathy, splenomegaly, paresthesias and hemorrhagic phenomena.

A mild anemia is often recorded. Leukocytosis is infrequent but in some cases there may be an increase in eosinophils, lymphocytes or monocytes. Creatinuria is a constant finding when there is moderate or severe muscle involvement. Other laboratory abnormalities which have been recorded include increase in serum globulin, proteinuria, hematuria and reduction in serum albumin.

The course is a progressive one to death in about half of the cases. However there may be remissions and exacerbations of activity of the disease. The terminal event may be respiratory insufficiency, cardiac failure or a complicating infection. It would appear that the majority of the patients who survive the first year may enter a very long period in which the process may become quiescent or remain mildly active.

**Diagnosis** When the classic features described are present they are usually sufficient when combined with muscle biopsy to make the diagnosis with certainty. Early in the course it may be difficult to distinguish this disease from the edematous stage of scleroderma or scleredema. Periorbital edema and muscle tenderness may mimic trichinosis and in other cases there may be a resemblance to polyneuritis, myasthenia gravis, muscular dystrophy, pseudo bulbar palsy, thyrotoxic myopathy, Addison's disease and periarteritis nodosa. In the acute form there may be symptoms similar to those of systemic lupus erythematosus such as facial erythema, vague arthralgias, fever and weakness and sensitivity to sunlight. However there are usually distinguishing features. There are transitional cases in which the clinical picture has seemed to fit one disease well only to have at a later stage the typical histological picture of the other. For example the atrophic dermal changes of scleroderma may be seen in patients with sys-

temic lupus erythematosus or dermatomyositis and in advanced scleroderma there may be extensive muscular involvement. However the associated findings, the laboratory examinations and the histological picture usually serve to make the diagnosis clear.

**Treatment** Symptomatic treatment should include rest in bed, suitable physiotherapeutic measures and special exercises to minimize contractures. Salicylates may be helpful in the relief of pain and tenderness but in the acute phase more potent analgesics may be necessary. In the early stages when activity of the process is evident, corticotropin, prednisone and cortisone may produce dramatic relief but large doses sufficient to produce the recognized features of Cushing's syndrome may be necessary over a period of several weeks. Striking objective improvement in muscle power may be brought about and sustained with maintenance therapy. A few patients have remained in remission when the dose of hormone was gradually reduced and then treatment discontinued after a period of several months. When advanced atrophy and fibrosis have developed there is no return of function after hormone administration.

## Polyarteritis

(*Periarteritis Nodosa*, *Polyarteritis Nodosa*, *Necrotizing Angitis*)

**Definition** Kussmaul and Maier introduced the term periarteritis nodosa in 1866 to describe a systemic disease characterized by visible nodules along the course of the medium sized muscular arteries. The lesions

of the cases of dermatomyositis there is an associated neoplasm of some type such as carcinoma of the breast stomach ovary or kidney. Such dermatomyositis is usually acute and is said to be potentially reversible with successful treatment of the neoplasm. It has been suggested that the disease is due to development of antibodies against the neoplasm which cross react with other tissue antigens.

As evidence of the infrequency of this syndrome only 38 proved cases have been observed in the Johns Hopkins Hospital since 1933. The youngest patient was two and the oldest seventy six at the time of onset, the largest incidence being in the fifth decade. There was no sex predominance and three of the patients were Negroes.

**Pathology.** Histologically the skin may reveal vacuolation of the epithelium perivascular lymphocytic infiltrations atrophy of the epidermis flattening of the rete pegs and edema or fibrosis of the cutis. These changes are not specific for this disease. The affected muscles may appear swollen and pale in color and have a firm consistency. The primary process is one of degeneration of muscle fibers but there may be a variable degree of inflammatory reaction. The sarcolemmal nuclei of altered fibers may be increased and vacuolization granular degeneration and fragmentation can be seen in many fibers. Perivascular accumulations of mononuclear cells may be present. In the acute stage there is active phagocytosis of involved fibers and hemorrhages may occur leading to the use of the term "hemorrhagic myositis." In the chronic form one sees vacuolated fibers which contain shrunken sarcolemmal nuclei and there is an increase in the endomysial collagen. Microscopic changes similar to those seen in skeletal muscle have been observed in the myocardium.

**Clinical Features and Natural History of the Syndrome.** Some observers have differentiated cases into two clinical types: (1) acute dermatomyositis which is more commonly seen in children and is characterized by an erythematous eruption edema tenderness swelling and weakness of the proximal muscles of the extremities fever and leukocytosis. Involvement of the respiratory muscles may lead to a fatal termination but the process may have a self limited course. (2) chronic polymyositis which runs a more chronic course begins in the peripheral limb muscles and is not associated with dermal involvement. However there are all gradations between these

two extremes and cases which begin acutely with erythema and edema of the skin and extensive muscle involvement may pass into the chronic stage with atrophy and fibrosis. The dermal and muscular involvement do not always parallel one another and there may be an interval of many months between the appearance of the cutaneous lesions and the evidence of muscle dysfunction.

The disease often begins with muscle tenderness followed by weakness and the appearance of cutaneous signs. Raynaud's phenomenon may be an early manifestation. The muscular involvement is not constant in its distribution and may be limited to one group such as the shoulder or pelvic girdle or may be generalized from the onset in which event the course is usually a fulminating one. The element of pain and tenderness seems to depend on the degree of edematous change and may be very intense slight or even absent. The muscles may at first feel doughy later become firm and finally show extensive wasting. Stiffness and weakness are usually complained of early and are often symmetrical in distribution. Later there is marked atrophy and fixation of joints may occur. Striated muscles in areas other than the limbs and trunk may be involved giving rise to such symptoms as diplopia dysphagia difficulty in respiration facial weakness and impairment of sphincter control. Heart failure may occasionally be present owing to similar changes in the cardiac muscle.

The areas most frequently involved by the mucocutaneous lesions are the face eyelids ears buccal mucosa V area of the neck and the skin overlying articulations. The eyelids may be swollen and have a characteristic heliotrope coloration due to the presence of small telangiectases. Important are the symmetrical cutaneous lesions overlying the small joints of the hands which may show edema a violaceous hue and telangiectases. Similar changes may be seen about the larger joints and when scaling is prominent may resemble psoriasis. As the lesions regress pigmentation may develop in some cases this may be so widespread as to resemble Addisonian discoloration. Cutaneous alterations may be present which resemble the changes seen in scleroderma. When there is extensive involvement lesions in various stages of development from acute erythema and edema to atrophy and pigmentation may be observed. Subjective symptoms such as pruritus are usually absent. As in lupus

affected vessels may show intimal proliferation leading to thrombosis and arterial obstruction with infarct formation. The artery may become distended into an aneurysmal sacculi and may even rupture. In some instances the vascular changes may be limited to the vessels of one system or to a few isolated organs with the result that no single clinical finding is invariably present. The lesions may be seen in all stages in any given case from acute ones to those which are completely healed.

In hypersensitivity angitis according to Zeek the smallest branches of blood vessels both arterial and venous are involved and the intense cellular reaction contains many eosinophils. The lesions in the individual case are the same age and no chronic or healed lesions are noted.

**Clinical Features and Natural History of the Syndrome.** The widespread nature of the vascular lesions reflects itself in symptoms and signs so variable and so often superficially unrelated that no standard clinical description can amply relate the polymorphic manifestations of these illnesses. In cases of periarteritis nodosa the general clinical picture presented may be that of (1) a nonspecific subacute or chronic pyrexial illness (2) an atypical abdominal illness (3) a primary renal disease or (4) a combination of polyneuritis and polymyositis manifestations. In the accompanying table are listed the principal signs and symptoms as recorded in several hundred reported cases. Fever occurs at some time during the course of the disease in almost every case. Approximately half of the patients describe a sudden onset accompanied by fever. The kidneys are frequently involved albuminuria and hematuria being common findings. Hypertension occurs in over half the cases. According to Rose and

hematuria. The elevation seems to be a sequel of renal polyarteritis or glomerulitis but it develops only during the healing stages of these lesions. Thus in contrast to the views of Knowles and Blankenhorn the hypertension is not a precursor of the disease but usually is a result of it. The recognition of hypertension as a complication of polyarteritis is important as it may be the presenting clinical feature and this syndrome should be suspected in all cases of severe or rapidly progressive high blood pressure associated with fever leukocytosis or unexplained lesions in other systems.

The frequency with which the characteristic arterial lesions of periarteritis nodosa are found in one or more of the abdominal viscera or the intestinal tract accounts for the common occurrence of abdominal pain which is often violent and maximal in the umbilical region or in the gallbladder area. Anorexia nausea vomiting and bloody diarrhea have been observed and thrombosis of mesenteric arteries may lead to infarction of the bowel. Such arteritic lesions may involve the appendiceal pancreatic and hepatic vessels as well resulting in a clinical picture simulating appendicitis hemorrhagic pancreatitis or hepatic necrosis. Mucosal ulceration with hemorrhage and perforation has been reported frequently.

A painful peripheral neuritis usually bilateral and often asymmetrical is a common finding particularly in the lower limbs. Many other signs and symptoms due to arteritic lesions in the nervous system have been noted including meningeal irritation due to subarachnoid hemorrhage facial palsy hemiplegia cerebellar signs visual disturbances headache vertigo and convulsions.

The vessels supplying the myocardium may be involved with the production of a large myocardial infarct or multiple small areas of necrosis. Frequent attacks of precordial pain may be noted and the picture of congestive heart failure may ensue. In hypersensitivity angitis heart failure has been associated with mild myocardial infarcts. Heart failure may also be associated with the severe hypertension which is often present. Pericardial tamponade may follow rupture of an aneurysm along a superficial coronary vessel.

Pain in the chest may be due to pleural vasculitis and a hemorrhagic effusion may result. Pulmonary vascular thrombosis leading to hemoptysis and excavation may simulate pulmonary tuberculosis. An "anaphylactoid pneumonia" has been described in cases which follow drug reac-

Symptoms and Signs of Periarteritis Nodosa With Frequency of Occurrence in 300 Cases

Fever	85	Jaundice	10
Abdominal pain	65	Convulsions	10
Hypertension	60	Eruptions	10
Edema	50	Diarrhea	10
Neuritis	50	Muscle soreness	10
Weakness	45	Leukocytosis	80
Weight loss	45	Albuminuria	60
Cough and dyspnea	40	Hematuria	40
Vomiting	30	Eosinophilia	25
Headache	30	Uremia	15
Precordial pain	25		

Spencer the blood pressure does not rise until after the appearance of proteinuria or

are segmental in their distribution and involve arteries throughout most of the body in varying degree so that the resulting clinical picture is one of polymorphic manifestations which may seem unrelated. Some observers have placed all of the pathological conditions of the vascular system characterized by inflammation and fibrinoid necrosis in the category of periarteritis nodosa including the angitis which follows an allergic reaction to a drug or foreign protein. Others have suggested "necrotizing angitis" as a better term to use collectively for all vascular lesions showing this type of histological picture.

**Etiology and Incidence** During the past few decades numerous observers have recorded vascular phenomena in association with allergic reactions of various types. Gruber first suggested that periarteritis nodosa might be a general hyperergic reaction to infectious or toxic agents to which the vessel walls had previously been exposed. In 1937 Clark and Kaplan described necrotizing vascular lesions accompanying serum sickness. Rich and Gregory found lesions similar to those seen in periarteritis nodosa in patients dying from serum sickness and allergic reactions to sulfonamides and iodine. These workers produced the lesions of periarteritis nodosa experimentally sometimes accompanied by glomerulonephritis in rabbits by the establishment of an anaphylactic state analogous to human serum sickness. Hawn and Jane way using bovine serum produced segmental arterial lesions in the rabbit which were similar to those which followed the injection of horse serum. Of interest was the production by the albumin fraction of lesions confined almost exclusively to arteries and by gamma globulin of lesions principally in the glomeruli and in a lesser degree in the heart. However in most cases of periarteritis nodosa there is no history of any type of allergic reaction either to drugs or foreign proteins. It has been suggested that various infectious agents may be etiological factors but little substantiating evidence exists.

Zeek and her co-workers believe that drug-induced lesions are different morphologically and in distribution from those seen in human periarteritis nodosa and state that vascular changes like those described by Kussmaul and Mauer have been produced experimentally by procedures that usually resulted in severe hypertension but did not cause hypersensitivity. They prefer the term necrotizing angitis for this entire group of arterial diseases and believe that

five types may be differentiated (1) periarteritis nodosa (2) hypersensitivity angitis (3) rheumatic arteritis (4) allergic granulomatous angitis and (5) temporal or cranial arteritis. Rose and Spencer believe that the presence or absence of lung lesions is a better basis for classification than the size of the involved vessels or the types of arteritis listed by Zeek. The possibility of an infectious background is rekindled by the finding in their cases of pulmonary arteritis that a respiratory illness diagnosed as bronchitic, pneumonic or asthmatic initiated the disease. In two thirds of the cases over a year elapsed before systemic polyarteritis developed. In many of their cases in which an association between a sulfonamide drug and polyarteritis was suspected the drug was given for a respiratory infection. In five of twenty-two cases a  $\beta$  hemolytic streptococcus was isolated and in addition 12 per cent had active rheumatic fever or a history of an attack.

The nature of so-called fibrinoid necrosis is fundamental to study of the pathogenesis of these various vascular lesions. It is generally believed that this type of reaction in connective tissue is not pathognomonic of allergy but is merely a nonspecific response to injury. Altschuler and Angevine have produced evidence that it represents the precipitation of acid mucopolysaccharides in the ground substance of connective tissue.

The incidence is difficult to estimate when no specific diagnostic procedure other than the inadequate one of muscle biopsy is available. Perhaps only a small percentage of the total instances of polyarteritis are recognized since selection on this present basis favors a high incidence of fatal cases. Lesions tend to heal spontaneously and on biopsy are seen in all stages of histological development.

It seems reasonable to conclude that there are a number of syndromes characterized by arterial inflammatory lesions and any sound classification will be impossible until more is known about etiology and pathogenesis. There is ample evidence however that this group of diseases is being recognized more frequently.

Males predominate with a sex ratio of 3:1. The peak age incidence is between twenty and fifty years.

**Pathology** In periarteritis nodosa the arterial lesions consist of necrosis, fibrinoid alteration and hyalinization of the media with a marked perivascular infiltration of mononuclear and polymorphonuclear cells but without foreign body giant cells. The

Since prognosis is much worse in the presence of hypertension one would expect the majority of the untreated to die in the year following diagnosis (twelve of nineteen). Of the treated patients fourteen were living one year after diagnosis but no firm conclusion can be reached because of the unsatisfactory nature of the controls.

In view of the rapid development of new therapeutic agents it is of importance that further information be obtained concerning the pathogenesis of periarteritis nodosa and so called hypersensitivity angitis and whether there is any fundamental difference between them that cannot be explained by the nature and time-course of the antigen antibody reaction.

## Cranial (Temporal) Arteritis

### (Temporal Arteritis Giant Cell Arteritis)

This disease is essentially an arteritis and periarteritis of the temporal vessels characterized by a cordlike thickening of the involved arteries the presence of palpable nodules along the vessels and painful areas over the temples and scalp.

Histologically there is proliferation of inflamed fibrous tissue of all layers of the affected vessels together with focal necrosis and granulomatous lesions associated with giant cell formation in the media. The marked fibrous tissue proliferation in the intima leads to narrowing of the lumen and often to thrombosis. The etiology is unknown but the onset in many cases follows an infection.

There may be involvement of other arteries including the carotid subclavian coronary renal mesenteric pulmonary femoral brachial and dorsalis pedis.

The onset is characterized by headache and other manifestations including ma-

laise weakness anorexia loss of weight night sweats muscle and joint aches and soreness mild anemia and leukocytosis. There may be pain in adjacent structures such as the scalp face jaws eyes and temporomandibular joints. The headache is boring in character usually more marked on one side severe at night and often intractable. Two to four weeks after onset the temporal arteries become prominent and tortuous and along their course raised painful tender nodules may develop. Pulsations later disappear. The severity of the illness is out of proportion to the visible signs. There may be enlargement of the cervical lymph nodes.

In the majority of cases the disease is disturbing but self limited lasting from two to thirty months. A variety of complications may ensue. Ocular difficulty develops in about 30 per cent of the cases. Pain photophobia diplopia oculomotor paresis or transient ptosis may occur and in more severe cases central retinal artery thrombosis or an ischemic optic neuritis with an edematous or pale papilla. The clinical picture may be that of an acute retrobulbar neuritis. Cerebral symptoms may develop with disorientation delirium hemiparesis or coma.

This disease can simulate a cerebral tumor other types of cerebral vascular disease retinal artery thrombosis of varied etiology sinusitis dental neuralgia or osteoarthritis of the cervical spine.

The chief value of the adrenocortical steroids in treatment is to control the progress of the arteritis as long as it is active and thus safeguard the degree of vision that remains or prevent the development of ocular complications. Blindness does not correlate with the severity of the temporal artery involvement so that all cases should be treated as soon as the diagnosis is made. All general symptoms disappear in a few days on steroid therapy including headache. In one series the final incidence of blindness was 11 per cent in steroid treated cases while in a matched series untreated and analyzed retrospectively it was 22 per cent. If there was loss of sight at the time treatment was begun no significant improvement followed steroid administration.

- Birkhead N C Wagoner H P and Shick F M Treatment of Temporal Arteritis with Adrenal Corticosteroids Results in 55 Cases in Which Lesion Proved at Biopsy JAMA 163 821 1957

tions The association of asthma together with paresthesias of the extremities and eosinophilia was noted by Rackemann and Greene More recently Churg and Strauss have described a syndrome characterized by severe asthma fever and hyper eosinophilia together with manifestations of vascular involvement in other organ systems which they have called allergic granulomatosis They feel that this is an entity apart from classic periarteritis nodosa and suggest that other allergic syndromes such as that of Loeffler may represent benign forms of allergic granulomatosis

Joint pains and myalgia have been frequently noted in periarteritis nodosa Muscle pain and soreness may be so prominent that when eosinophilia is also present trichinosis is suspected Joint swelling is rarely seen and often the tenderness or pain is associated with peripheral neuritis

In periarteritis nodosa the ovaries testes and epididymes are frequently involved Extensive vasculitis of the bladder may lead to gross hematuria and dysuria as an early manifestation of the disease

A variety of cutaneous lesions may be seen in periarteritis nodosa as well as in hypersensitivity angitis These include scarlatiniform eruptions urticaria angio neurotic edema vesicular and bullous lesions The latter may become necrotic and ulcerate involving large areas of skin

Leukocytosis is often a prominent feature and in some cases a conspicuous eosinophilia is present A severe anemia may develop and marked elevation of the sedimentation rate is common

The course of periarteritis nodosa is variable The onset may be insidious or sudden due to a vascular thrombotic lesion The disease is usually fatal but cases have been reported which were characterized by remissions long intermissions and exacerbations Complete recovery may take place from hypersensitivity angitis In both situations healing may occur clinically as well as histologically but when there is extensive involvement of the pulmonary cardiac renal or intraabdominal arteries recovery is rare

**Diagnosis** The diagnosis may be difficult as proof is dependent on histological evidence As the disease progresses many regions of the body may be involved and the multiplicity of signs and symptoms may suggest the correct diagnosis From the diversified symptomatology which has been described it is evident that periarteritis may simulate a great many other diseases

When a biopsy is taken the skin and subcutaneous tissues as well as the muscle should be sent for microscopic section As the lesions in the vessels are segmental in distribution many sections must be made

It has been stated that the vascular lesions in polyarteritis are characterized by inflammation with marked cellular reaction in systemic lupus by necrosis with a peculiar fibrinoid change and in rheumatoid arthritis by an overgrowth of vascular elements Cases may be seen in which the manifestations of these syndromes both clinical and histological are present simultaneously In some of the clinical variants such as Wegeners syndrome in which there are necrotizing lesions in the respiratory tract generalized arteritis and focal glomerulitis and in "malignant rheumatoid arthritis" all of these tissue changes may appear in well developed form The increasing frequency with which the lesions of periarteritis nodosa are being reported in patients with rheumatoid arthritis has been a cause for concern in view of the possibility that this may represent a deleterious effect of long term adrenal steroid administration

**Treatment** Treatment in the past has been for the most part symptomatic Every effort should be made to exclude any antigens that might be responsible Care should be taken in following the course of any patient receiving a drug to which manifestations of hypersensitivity may develop

Immediate relief of many of the manifestations of periarteritis are noted after the administration of adrenocorticotrophic hormone and the adrenal hormones All histological signs of inflammation may disappear within a few weeks In the process of healing fibrous obliteration of the lumina of vessels may occur with resulting infarction particularly in the kidneys heart and intestinal tract Occasional cases have been reported in which complete spontaneous remission took place and the only difference in these cases and those treated with the hormones is the rapidity and extent of the healing

To determine the effect of adrenal steroid administration on length of survival Rose and Spencer compared the results in seven teen cases treated with cortisone since 1950 with nineteen control cases retrospectively analyzed in the precortisone period (1941 to 1950) The groups were similar with the important exception that hypertension was more common in the untreated group at the time of diagnostic biopsy (42 per cent) than in the treated group (6 per cent)

Since prognosis is much worse in the presence of hypertension one would expect the majority of the untreated to die in the year following diagnosis (twelve of nineteen). Of the treated patients fourteen were living one year after diagnosis but no firm conclusion can be reached because of the unsatisfactory nature of the controls.

In view of the rapid development of new therapeutic agents it is of importance that further information be obtained concerning the pathogenesis of periarteritis nodosa and so called hypersensitivity angitis and whether there is any fundamental difference between them that cannot be explained by the nature and time-course of the antigen antibody reaction.

## Progressive Systemic Sclerosis

(*Scleroderma Sclerema Adultorum Derma to sclerosis*)

**Definition** Progressive systemic sclerosis is a disease involving the collagenous connective tissue which may cause widespread symmetrical leathery induration of the skin followed by atrophy and pigmentation. The cutaneous lesions are merely the external manifestation of a systemic disease and the muscles bones mucous membranes heart lungs intestinal tract and other internal organs may be involved by the same process resulting in functional impairment such as heart failure or pulmonary insufficiency.

**Etiology and Incidence** The specific etiology of scleroderma is unknown. Similar changes in collagen tissue may occur in systemic lupus erythematosus rheumatic fever rheumatoid arthritis and serum sickness but the pathological process is not of sufficient specificity to serve as a common denominator for the classification of these diseases. The possible role of infections and of abnormalities of certain endocrine glands has been postulated but no consistent relationships have been noted.

Both the localized form known as *morphea* and the generalized disease are relatively uncommon. Scleroderma appears most frequently in the middle period of life and females are more frequently affected than males.

**Pathology** Histological studies show that scleroderma is primarily a collagenous tissue alteration thus accounting for the stiffness and hardness of the affected structures. There is at first swelling of collagenous intercellular substance which later becomes dense and sclerotic. The vascular lesions show thickening of the intima often with fibrinoid degeneration and occlusion

resembling those seen in systemic lupus erythematosus and are thought by some to have a relationship to the sclerodermatous alterations in the skin. Later there is atrophy of the epidermis including the appended structures. Calcification develops in some cases. Similar changes occur in collagen tissue in other organs including the heart lungs and gastrointestinal tract.

Characteristic renal lesions have been reported in which there is thickening of the intima principally of the interlobular arteries as a result of the deposition of a mucoid substance which is metachromatic. With progression of the lesion the vessel lumen is narrowed or occluded by the formation of concentrically laminated fibrous tissue leading to patchy areas of cortical necrosis. This sequence of the deposition of metachromatic ground substance preceding the fibrogenesis of collagen is characteristic of both embryogenesis of connective tissue and its formation in wound healing. Experimentally certain naturally occurring mucopolysaccharides induce active fibrogenesis. It has been postulated that the formation of an abnormal mucopolysaccharide in the body might be the basis for the development of this disease. However these changes in the kidney as well as the fibrinoid lesions in the arteriolar and glomerular thrombi are similar to those seen in accelerated nephrosclerosis.

**Symptoms and Signs** The focal form of the disease is characterized by indurated lesions found on the trunk extremities or neck which may follow the distribution of the peripheral nerves. This is a benign process which only rarely may precede the development of diffuse cutaneous or visceral involvement. In the linear form firm irregular bands several centimeters in width may be distributed over the skin of the extremities forehead and scalp but seldom the trunk. There may be involvement of underlying muscle and the development of contractures.

In the diffuse or systemic disease the cutaneous changes pass through several stages the first of which is a brawny edema which commonly starts on the hands and feet and later involves the face neck and often the trunk. The nonpitting edema gives the skin a puffy white appearance with smoothing of the normal folds. In the second or indurative stage the skin becomes smooth waxy leathery and tight so that it cannot be lifted from the deeper structures. This may be most prominent on

the fingers dorsum of the hands and the ankles. The face becomes masklike with the expression fixed. Constitutional manifestations such as weakness and loss of weight are common and joint pains and fever are prodromal symptoms in many cases. Raynaud's phenomenon and sclerodactyly often associated with dysphagia due to esophageal involvement may be present for years before cutaneous thickening in other areas is noticed. This has been referred to as the acrosclerotic form. The Raynaud's phenomenon may be of the anemic type which is a chronic condition different from the true spastic phenomenon characterized by sudden attacks.

As the disease advances to the atrophic stage the skin becomes thinner, smoother and completely adherent to the shrunken muscles. The movement of joints is progressively restricted until the patient resembles a living mummy. There may be extensive brownish pigmentation of the skin as well as patchy areas of depigmentation. In some cases calcium is deposited in the diseased portions usually about joints. Other developments include anhidrosis, coldness of the digits, loss of hair, telangiectasia and the appearance of indolent painful ulcers. Lesions may also be noted in the mucous membranes with painful induration of the tongue as well as of the gums. In some cases dyspnea, cyanosis and edema are attributable to involvement of the heart muscle by this peculiar type of fibrosis. Diffuse pulmonary scleroderma may result in severe functional impairment with the syndrome of "diffusion fibrosis" due to impairment of oxygen transport across the alveolo-capillary membrane similar to that seen in sarcoidosis and beryllium intoxication. Ventilatory function may also be impaired if involvement of the skin and muscles restricts normal motion of the chest. Disturbances in thyroid, pancreatic, pituitary and adrenal function have been described by various observers although these organs may show no histological lesions characteristic of this disease. The difficulty in swallowing is the result of atrophy and sclerosis of the esophagus leading first to dilatation and loss of normal peristaltic movements. Later there may be partial obstruction with the development of a chronic esophagitis. When there is diffuse involvement of the intestinal tract, pain, nausea, vomiting, diarrhea or constipation may develop. Deterioration of renal function complicated by a malignant type of hypertension may develop as a late mani-

festation. Severe hypertension of sudden onset may occasionally appear before there are signs of renal insufficiency. The association of cataracts, premature graying and baldness, calcification in subcutaneous tissues, osteoporosis, hypogonadism and scleroderma is heredo-familial and is known as *Werner's* or *Rothmund's* syndrome.

In contrast to other connective tissue diseases such as systemic lupus erythematosus, hematological and biochemical alterations are not regularly present. There may be a mild anemia and increase in the sedimentation rate. Serum albumin may be below normal levels and occasionally some elevation in serum globulin is noted. The urine may contain albumin, red cells, white cells and casts. Roentgenograms may reveal diffuse osteoporosis and destructive lesions of bone have been described. Involvement of the heart, lungs and intestinal tract may be recorded also by radiological and electrocardiographic studies. The roentgenographic appearance of the lungs is usually a diffuse linear infiltration which may be more prominent in the lower half of the lungs. There may be dilatation of the esophagus with marked delay in the descent of barium. A triangular appearance of the heart and limited movements on fluoroscopy may suggest the changes noted in pericardial effusion and myxedema heart. The electrocardiogram may show change in rhythm, T wave alteration and other evidence indicative of myocardial involvement. These changes are not specific or diagnostic of scleroderma.

**Diagnosis.** The typical case presents no difficulties in diagnosis but sclerodactyly in the early phases may be diagnosed as Raynaud's disease or the joint pains as some type of arthritis. Fever, arthralgia and erythema of the skin may suggest systemic lupus erythematosus and the distinction from dermatomyositis is at times difficult. In the stage characterized by edema, differentiation must be made from scleredema which is a relatively benign condition. Probably the majority of cases of scleredema are diagnosed as scleroderma and this may account for many of the instances in which dramatic improvement in scleroderma is believed to have occurred. The hands which are so uniformly involved in scleroderma are almost always spared in scleredema. Scleredema does not progress to atrophy, contractures or pigmentary changes and spontaneous remission is the rule. There may be pleural or pericardial effusion in scleredema but seri-

ous involvement of the heart lungs esophagus or intestinal tract is not characteristic as in scleroderma

Other conditions which may be characterized by some type of cutaneous edema are in most instances easily differentiated. These include trichinosis myxedema and edema of cardiac or renal origin.

**Prognosis** In the localized type (morphea) healing takes place leaving a smooth hard depressed area in the skin. Scleroderma of the slowly advancing generalized type may pass through periods of activity and remission during which extension to a new area may be accompanied by remission in areas involved earlier. Disability may finally be extreme and death in the chronic form often results from some intercurrent infection or from specific involvement of such areas as the heart lungs or kidneys.

**Treatment** The long list of therapeutic agents tried in this condition including various metals hormone preparations and peripheral vasodilators makes it obvious that no specific treatment has been discovered. Local heat massage hydrotherapy and softening ointments may be beneficial. In the vascular form with vasospasm and a formal vasodilatory response protection from cold vasodilator drugs and sympathetic ganglionectomy may be recommended according to the principles and with the limitations followed in the treatment of Raynaud's disease. A number of cases have now been treated with pituitary corticotropin or cortisone. With aggressive therapy temporary beneficial effects may be obtained in the early phases but treatment after the development of atrophy and contractures has not been helpful. No improvement in pulmonary function has been observed to follow hormonal therapy.

Most important is the intelligent utilization of physiotherapy to prevent deformities resulting from contracture and to maintain muscle function to the greatest possible extent.

## Scleredema

### (Scleredema Adultorum of Buschke)

This rare condition which usually follows an acute infection and has a benign course is characterized by a brawny edema of the skin which may resemble closely the early stage of scleroderma. The dermis is thickened and there is a moderate perivascular cuffing with mononuclear cells. In the deeper layers the collagen fibers are hypertrophied and swollen. A mucin-like material which stains with cresyl violet may separate these enlarged collagen bundles producing a fenestrated appearance. Similar changes have been described in other organs.

Scleredema has been considered to be a diffuse disease of collagen. It usually develops one to six weeks after an infection which is most frequently of streptococcal origin. The disease is predominantly one of females. The majority of cases develop in childhood and early adult life but the diagnosis has been made in the neonatal period and as late as the seventh decade.

The characteristic waxy brawny edema of the skin usually appears abruptly although a brief prodromal period with slight fever malaise and myalgia has been described. In the majority of cases the neck is involved first but within one to two weeks there is spread to the face chest abdomen and extremities. The hands and feet are almost always spared. There may be an erythematous blush to the involved skin but pigmentation and atrophy do not develop. There is no pitting on pressure and the skin is difficult to pick up. There is a sense of being "hidebound" and when the chest is involved dyspnea may result from the restriction of thoracic movement. Involvement of the tongue and pharyngeal tissues results in dysphagia and dysarthria. Parotid swelling has been described and the occasional development of hydrarthrosis pleural effusion and hydropneumothorax is cited as evidence of the systemic nature of this disease.

Scleredema and the early stage of scleroderma may be easily confused. The onset of scleroderma may also follow an infection and the histological changes seen at this stage may not be distinctive. In scleredema the induration is more prominent in the superficial layers of the cutis and atrophy pigmentation and telangiectasia do not develop. In contrast to scleroderma

involvement of the hands and feet = rare. The early phases of dermatomyositis may resemble scleroderma so closely that a final diagnosis must be delayed until the more distinctive features appear. Other conditions such as trichinosis, myxedema and edema of cardiac and renal origin are easily distinguished by the associated manifestations.

There is resolution of the edema in from six to eighteen months in most of the cases. However, the disease may remain essentially static for years or may regress in certain areas leaving islands of edema which slowly resolve.

As in scleroderma, many forms of treatment including artificial heat, hormonal substances, vasodilators and antihistamines have been tried but thus far none may be considered specific. The general tendency to spontaneous recovery makes evaluation of therapy difficult. In cases treated intensively with pituitary corticotropin or adrenocortical steroids, there may be partial clearing of the edema, but the response is usually not dramatic.

### Thrombotic Thrombopenic Purpura

This syndrome is characterized by thrombocytopenic purpura, hemolytic anemia and bizarre symptoms and signs of central nervous system involvement. The histological picture consists of occlusions of small arterial vessels by an amorphous acidophilic material. It was first thought that these were platelet thrombi, but endothelial damage appears to be the first event and it has been demonstrated that the material is composed of an immunochemically reactive derivative of fibrinogen or fibrin. The thrombotic lesions are commonly seen in the myocardium, adrenals, renal cortex, pancreas and gray matter of the brain. They show various stages of healing and recanalization may be seen. In some cases there is the simultaneous presence of the

vascular lesions of systemic lupus erythematosus and polyarteritis.

The disease usually presents as an acute process with a fatal outcome in days or weeks but occasionally it is a chronic relapsing disease lasting for months to years, appearing in episodic bouts and ending in death from an acute exacerbation. The clinical and laboratory manifestations of the thrombocytopenic purpura are similar to those seen in purpura due to other causes.

The onset is usually associated with malaise, headache, fatigability, myalgia or arthralgia. Fever is regularly present and nausea, vomiting and abdominal pain are frequent. Pallor is conspicuous, icterus when present is usually mild. Hepatosplenomegaly and lymphadenopathy may be observed. Cardiovascular manifestations include tachycardia, gallop rhythm and a systolic bruit. Psychotic behavior may be the presenting feature and among the nervous system manifestations are irritability, confusion, delirium and stupor. Convulsions occur as well as focal signs including cranial nerve palsies, hemiplegia and aphasia. The manifestations may wax and wane in severity and are often transitory.

The anemia is normochromic and normocytic and the hallmarks of a hemolytic process are present. The abnormally shaped erythrocytes noted are designated as "helmet cells," "schizocytes" or "bizarre spherocytes." In the occasional case there is a positive Coombs test. The white cell count may be elevated with a leukemoid reaction. L.E. cells have been demonstrated in a few instances. At times the diagnosis is made by noting the typical vascular pattern in paraffin sections of particles obtained on bone marrow puncture.

Transfusions do not elevate the erythrocyte level for a prolonged period unless a spontaneous remission occurs. Adrenocorticotrophic hormone or adrenocortical steroids have not had a dramatic effect but may be tried in large doses. In two cases there has been relief of the hemolytic process after splenectomy.

# Diseases Due to Physical Agents

## Heat Exhaustion, Heat Stroke and Heat Cramps

*Heat exhaustion* is a physiological breakdown following exposure to heat and is characterized principally by peripheral vasomotor collapse. *Heat stroke* on the other hand has for its distinguishing manifestation an extreme elevation of body temperature. *Heat cramps* are muscular cramps due to excessive salt loss. Although manifestations of two or even all three of these conditions may coexist the mechanisms by which they are produced are quite different.

Heat exhaustion results usually from physical exertion in a hot environment when vasomotor control and cardiac output are inadequate to meet the needs of increased skin circulation in addition to muscle and cerebral circulation. It may be precipitated in even the most fit man by heavy enough work or a severe enough environment. The severity of the environmental heat stress is determined by temperature, humidity and wind velocity. The wet bulb temperature is probably the best single index paralleling physiological stress.

Heat exhaustion is a nonfatal physiological disturbance unless complicated by coexisting disease. The factors in normal adaptation are important in understanding the morbid physiology. When a man is exposed to a hot environment a considerable part of his circulation must be directed into the blood vessels of the skin in order to radiate heat from the surface and to support activity of the sweat glands. The ease of these adaptations is rapidly enhanced by repeated exposures to work in

the heat, a process known as acclimatization caused at least in part by increased adrenocortical activity and manifested by increased blood volume, better vasomotor control and more efficient sweating. Obviously even a minor degree of dehydration will prevent maximum cardiovascular adaptation and so predispose to heat exhaustion.

Salt deficiency from any of several causes predisposes to heat exhaustion. Restricted salt intake or lack of supplemental salt during very heavy sweating is a common cause of salt deficiency. Recently described excessive salt concentrations in the sweat of patients with fibrocystic disease of the pancreas and in some normal members of their families illustrate another rather special mechanism of salt depletion.

Faintness usually with subjective sense of palpitation is the predominant symptom. Nausea, vomiting, syncope, headache and restlessness are common. Other symptoms may appear from underlying cardiac or other disease.

The patient who has collapsed in the heat and is perspiring freely almost surely has heat exhaustion and not heat stroke even though his temperature is somewhat elevated. Under general supportive treatment he will usually recover consciousness promptly unless dehydration, salt deficiency, cardiovascular disease or some other complicating condition is important in the picture. In older patients a cardiovascular complication should be suspected if the symptoms persist.

The prognosis of simple heat exhaustion is invariably good and the treatment is simple. Rest in a comfortable environment

and mildly salted fluids by mouth as tolerated will usually suffice. Occasionally when vomiting is severe and cardiac disease is absent intravenous injection of 1000 ml of 5 per cent glucose in physiological saline may hasten recovery. The most important phase of treatment is that related to cardiac or vascular disease which may manifest itself.

**Heat stroke** is a failure of adequate heat elimination almost always related to a breakdown of the sweating mechanism. It may occur whenever heat regulation is dependent on sweating for long periods of time. Experimentally the rate of sweating in normal persons has been found to decrease progressively during work in the heat and finally to lead toward real deficiency of sweating. In heat stroke this process has apparently gone on to complete breakdown of the mechanisms of temperature regulation to complete cessation of sweating and extreme elevation of body temperature.

At autopsy the important and primary tissue damage is in the central nervous system consisting in edema and in severely involved areas destruction of nerve cells chiefly in the cerebral cortex. Other changes are probably related to the secondary vasomotor shock which occurs in severe cases: congestion, edema and hemorrhages in various organs.

Although the exact mechanisms of maintenance of sweating are not known it is clear that they fail in incipient heat stroke and the process behaves like a local fatigue of the glands. Heat stroke rarely occurs if relief from sweating is afforded during a part of the day such as in desert areas with cool nights or where air-conditioned sleeping quarters are available. In extremely hot environments the development of full-blown stroke may be a matter of a few minutes after cessation of sweating since all the normal heat loss under these conditions may be by evaporation of sweat. Dehydration is not a factor in fact superhydration has been reported. Leukocytosis is the rule often above 20,000 per cubic millimeter; diminution of platelets is common in severe cases.

The patient may occasionally be aware of cessation of sweating but often he is not. Sensation of extreme heat is the rule. The first overt symptoms are often those referable to the central nervous system: mental confusion, staggering gait, headache, delirium or coma. In the early phases the circulation is maintained (rapid full pulse) but soon a stage of vasomotor col-

lapse supervenes with low blood pressure and rapid weak pulse.

The *diagnosis* of heat stroke is no problem in the classic instance with warm dry skin temperature of 105° F or higher, history of long exposure to heat, lack of evidence of other cause and coma or near coma. The chief confusion is with other diseases of the central nervous system causing coma and hyperpyrexia and occasionally with overwhelming sepsis without external manifestations or terminal liver disease. In some instances therapy to lower the temperature should be given before a sure diagnosis is made.

True heat stroke calls for heroic measures and is one of the few true medical emergencies. The aim of treatment is to reduce the body temperature to a safe range (102° F or lower) as rapidly as possible since brain damage is a function of both temperature and time. Total immersion in an ice bath or in water as cold as possible is probably the most efficient method of cooling. The alleged danger of heat retention from peripheral vasoconstriction and of increased shock has not been supported experimentally or clinically. Evaporative cooling by sprays and fans is effective provided the environment is cool and dry enough to allow rapid evaporation. An important adjunct often neglected is vigorous massage of the extremities during the cooling to overcome the peripheral stagnation regularly seen and to allow the more rapid transfer of heat. Vigorous cooling should be stopped when the rectal temperature reaches 102° F but may need to be reinstituted if the temperature rises again. Intravenous fluids should be given with care and only with definite indications because of the dangers of pulmonary edema. Persistence of coma and shock after cooling probably means severe brain damage and therapy is often disappointing. Irregularity of temperature regulation is to be expected for several days in those who recover.

*Prognosis* is wholly a function of the promptness of treatment. All untreated patients will die. Probably all would recover if heat stroke were detected early and treated vigorously. Most of those who have recovered retain some intolerance to heat. Late effects of brain damage are possible but have not been reported frequently.

**Heat cramps** are painful contractions of various skeletal muscles, a symptom most commonly seen among manual workers in hot environments whose body fluids have been depleted of sodium chloride by unre-

placed heavy losses (up to 20 gm a day) in sweat. The diagnosis is made by a marked lowering of plasma chloride (often to 90 mEq per liter) in the presence of the clinical symptoms. It is evident that factors other than simple salt depletion are acting in this condition since the symptom of cramps is only occasionally seen in patients with cardiac or hepatic disease with a similar degree of salt depletion from low salt diet and diuretics. The cramps are specifically relieved by the replacement of salt (and water). The intravenous administration of 600 to 1000 cc of normal saline may be necessary to start relief of acute symptoms. More important is prevention which is most surely achieved by adding 0.1 per cent sodium chloride to drinking water. Heavy salting of food and the use of salt tablets are effective but more difficult to enforce.

## Decompression Illness

### (Caisson Disease)

This term refers to the group of symptoms produced by the sudden reduction in pressure of the atmosphere. It is seen (1) among workers in compressed air after return to atmospheric pressure (caisson workers, tunnel workers and deep sea divers) or (2) on rapid ascent in open airplanes to heights usually above 25,000 feet. The recent popularity of deep diving as a sport has exposed a larger number of persons, many of them unwarned and untrained to the possibility of decompression illness. It should be noted that in all instances the symptoms occur during or after an abrupt drop in atmospheric pressure, always to at least one half of the initial pressure and usually to one third or less. Since the pres-

sure in water increases one atmosphere for each 33 feet in depth, dives of more than 60 to 70 feet if prolonged introduce some hazard in this respect.

**Etiology.** All the manifestations except an occasional symptom are clearly due to the evolution of bubbles of nitrogen in the tissues and blood stream. The nitrogen in solution at the higher pressure is freed by the lowering of pressure. Nitrogen is the gas chiefly concerned because the pressure change of this gas is greatest and because oxygen and carbon dioxide diffuse rapidly and chemically combine more readily although the latter gases do diffuse into nitrogen bubbles when once formed. Bubbles cause symptoms by plugging small vessels and by the pressure of their expansion, particularly in confined regions.

**Morbid Anatomy.** Actual bubbles have been demonstrated only rarely. The usual cause of death is damage to the central nervous system, most severe in the spinal cord, especially the lower thoracic region. In the early stages there are areas of non-specific softening, later replaced by gliosis. Frequently the pathological changes are more widespread than suspected from clinical findings.

Bone changes are those of small sterile infarcts. In sudden deaths there is frequently intense congestion of all the internal organs.

**Pathological Physiology.** The amount of nitrogen dissolved in the tissues of the body at any pressure is considerably more than would be dissolved in a similar volume of water. This results from the greater solubility (five times as great) of the gas in fat than in water. The high lipid content of the central nervous system is the chief factor causing the vulnerability of that tissue.

Gradual reduction in the pressure of nitrogen will result in harmless diffusion of dissolved nitrogen from the tissues into the blood stream and elimination by the lungs. It is only by marked reduction in pressure (to one half or greater) that bubbles may form. Even then a solution (or the tissues) may remain supersaturated unless disturbed. Thus trauma and exercise predispose to bubble formation (and symptoms) and often determine the site. The circulation of the tissues is another important factor; relatively ischemic tissues will retain nitrogen longer.

Nitrogen may be removed prophylactically from the tissues by reducing the nitrogen content of the gas breathed, with out danger of bubble formation. Thus

breathing 100 per cent oxygen for 3 hours before high altitude ascent will practically eliminate the incidence of symptoms. At pressures above two atmospheres however oxygen is highly toxic and therefore its use in compressed air work must be limited to an aid in the later stages of gradual decompression. Helium chiefly because of its rapid diffusion has become an important replacement for nitrogen in work at very high pressures such as in deep-sea diving.

**Symptoms** The onset of symptoms occurs usually from a few minutes after decompression to three hours later. By far the most common manifestation is pain in joints, muscles or periarthral tissue (the "bends") coming on usually suddenly in one or several joint regions and varying in intensity from a mild ache to a tearing, excruciating pain. Mild pains may disappear with rubbing. Very severe pain may lead rapidly to collapse.

Manifestations in the skin considered among the mild forms of the disease consist in itching either mild or severe usually with blotchy purplish erythema, sometimes with a mild degree of edema and occasionally with palpable crepitation.

Neurological symptoms are of grave importance. The lower extremities are the chief site. They may vary from mild paresthesia and weakness to total paralysis. Loss of control of bladder and rectal sphincters is almost invariable even with little other paralysis. Symptoms from higher cord lesions are much less common and rare from brain damage.

Symptoms from bubbles in the lung capillaries (the "chokes") are often indicative of a severe form of the disease. The patient complains of inability to take a satisfactory deep breath, constriction of the chest and a dry cough. Severe symptoms may progress rapidly to general collapse resembling asphyxia.

In severe forms of the disease resulting from accidents and sudden escape from high pressures, rapid collapse and sudden death may occur without premonitory symptoms.

This description is more strictly that of decompression after work in compressed air. In decompression to high altitude involvement of the nervous system is much less frequent; otherwise the symptoms are quite similar.

**Diagnosis** Correct diagnosis depends entirely on a history of recent exposure to compressed air. The high altitude syndrome will be met only during high altitude flight. Without adequate history the condition

cannot be surely distinguished from other conditions causing muscle and joint pain or spinal cord disease. Occasionally abdominal pain due to decompression might be confused with acute peritonitis.

It is well to distinguish carefully the symptoms of decompression illness from other symptoms due to pressure change. Painful ears and sinuses occur chiefly on increase in pressure. Nitrogen at high pressures has a narcotic effect seen again on increase not decrease in pressure. Intestinal gases may cause pain by simple expansion during decompression.

**Treatment and Prognosis** The sole effective treatment is recompression and gradual decompression. At high altitudes descent to 20 000 feet will usually suffice. The syndrome after compressed air requires a compressed air chamber in which the patient should be recompressed to his original working pressure. Except in some instances of cord damage, symptoms will usually disappear provided treatment is prompt enough.

Decompression after relief or control of symptoms should be gradual, usually lasting 2 to 3 hours and recompression again is indicated by any recurrence of symptoms. Details of management may vary markedly. Breathing oxygen during the later stages of decompression helps to remove nitrogen.

Prognosis is invariably good if there is no cord damage. Even then prompt recompression is often successful. Recovery of cord function after more than transient damage is variable; some patients with complete physiological cord transection make a gradual complete recovery, others are permanent paraplegics. Other residual defects are related to the bones which may show permanent radiographic change of "aseptic infarction" at the ends of long bones and be the site of secondary hypertrophic changes.

Medical management of the workers by elimination of elderly, obese and particularly susceptible men and by well controlled slow decompression after work periods has reduced and can continue to reduce both the incidence and severity.

## High Altitude Sickness

Man ■ exposed to high altitude in two quite different situations in airplane flight and in residence or climbing in high mountainous areas The illnesses associated with these two modes of stress are conventionally discussed separately However there is logic in a combined presentation provided the discussion is limited to the effects of low barometric pressure The physiological stimulus is essentially the same although the speed of onset of the stimulus and its duration are usually quite different The reader may need to consult specialized texts in aviation and mountain medicine regarding the various associated stimuli such as acceleration motion cold etc

The relation between altitude and barometric pressure is readily seen in Figure 47 It will be noted that barometric pressure is approximately halved at 18 000 feet and cut to one third at 28 000 feet Since the air is of constant composition within the range of airplane travel the partial pressure of oxygen exactly parallels the barometric pressure However this parallelism does not extend to alveolar oxygen pressures because of the introduction of water vapor and carbon dioxide in the alveolar spaces Regardless of the altitude the water vapor pressure in the alveoli ■ 47 mm of mercury The alveolar carbon dioxide pressure although lowered by hyperventilation at altitude amounts to 25 to 30 mm of mercury The combined pressure of carbon dioxide and water of over 70 mm of mercury causes the alveolar O pressure to decrease more rapidly than the barometric pressure In theory at least the alveolar O pressure is zero at a barometric pressure of approximately 70 mm of mercury even when pure oxygen is breathed

The relationship between alveolar pressure and altitude while breathing air or oxygen is shown in Figure 48 The same figure also shows the arterial oxygen saturation under the same conditions Because of the shape of the curve of affinity of hemoglobin for oxygen the arterial oxygen saturation

falls off very gradually as the alveolar PO is reduced and then more rapidly Altitudes below 5 000 feet cause almost no arterial hypoxia between 5 000 and 10 000 feet the hypoxia is slight at higher altitudes successive increments in altitude have increasingly greater effects

*Acute altitude sickness or acute mountain sickness* is the syndrome occurring immediately or after ■ few hours exposure to altitude high enough to cause significant hypoxia In any one individual the symptoms will depend on the circumstances of the exposure and the altitude attained In airplanes the first symptom ■ usually an impairment of mental function rather similar to that induced by alcohol or marked lowering of blood sugar Fine judgment is earliest affected disorders of speech and of delicate coordination appear at somewhat higher altitudes The person so exposed may be unaware of any disorder or may experience some lightheadedness

In mountain exposure the first symptom is likely to be breathlessness especially during exertion it may appear at lower altitudes than in airplanes because physical exertion is more commonly required on mountains than in airplanes Arterial hypoxia of 85 to 88 per cent saturation regularly stimulates pulmonary ventilation through the carotid and aortic bodies but the hyperventilation so induced may be subjectively felt only during exertion Doubling of pulmonary ventilation at rest may not cause any awareness to the subject Along with the early breathlessness at moderate altitude the person may have mild cerebral symptoms (lightheadedness etc) due in part to the alkalosis of hyperventilation

If the exposure is continued for several hours headache malaise and in severe cases prostration may supervene People vary markedly in their susceptibility to these symptoms The reasons for differences in susceptibility among young normal persons are poorly understood As might be expected older people and patients with cardiovascular disease cerebral vascular disease and chronic diffuse pulmonary disease show greater susceptibility to symptoms which may be serious or even fatal Medical advice in regard to airplane or mountain travel for older people or patients with pulmonary or vascular disease can not be generalized specific knowledge of the expected altitude exposure and of the patient's clinical status is necessary Modern commercial aircraft are almost all pressurized so that cabin pressure ■ kept at

the equivalent of 1000 to 8000 feet altitude. Stress of modern airplane travel is likely to be greater from anxiety than from altitude. Mountain travel or residence is apt to be a greater stress for the above group of patients than airplane travel partly because of the greater exertion likely to be involved.

The syndrome of acute altitude sickness at moderate altitudes usually subsides in a few hours or days. For an understanding of this phenomenon as well as of reactions at

higher altitudes it is necessary to consider the process of altitude acclimatization.

The first and most striking change in acclimatization relates to pulmonary ventilation. Acclimatized persons breathe more deeply and slightly more rapidly than the unacclimatized with the result that their alveolar oxygen pressure is higher. In other words the gradient in oxygen pressure from the atmosphere to the alveoli is reduced. At least in part these advantageous changes are caused by the renal compensations of

FIG 47 Relationship between atmospheric pressure and altitude

† Aucanquilcha Chile highest permanent habitation

FIG 48 The alveolar oxygen tension and the percentage oxygen saturation of the arterial blood at various altitudes while breathing atmospheric air and while breathing oxygen (Armstrong H. Principles and Practice of Aviation Medicine 3rd ed Baltimore Williams and Wilkins Company 1952)

chloride retention which allows a reduction of plasma bicarbonate with minimal elevation of pH during hyperpnea. Prior to this phase of acclimatization the respiratory drive from hypoxia through the carotid receptors is reduced by the respiratory depression from alkalosis through the respiratory center.

Another pulmonary change of probable importance is an increase in the pulmonary vascular diffusing surface as measured by figures for diffusing capacity. The mechanism of this adaptation is not wholly clear.

Early studies of altitude acclimatization emphasized polycythemia as the mode of adaptation. This change is real but of limited physiological significance. The highest values recorded are in the order of a 50 per cent increase in oxygen-carrying capacity of residents on the highest Andean plateaus. Values for residents at lower altitudes and for temporary residents in the Andes are much lower. It is evident that full acclimatization in this regard takes many months. If we consider as Riley emphasizes that acclimatization is the sum total of adaptations whereby the gradient of oxygen between the atmosphere and the tissues is reduced, it can be calculated that polycythemia may reduce the gradient by 2 or 3 mm of mercury whereas hyperventilation may reduce it 10 to 15 mm of mercury. It is doubtful that the full theoretical advantage of polycythemia is gained because of the increased viscosity of polycythemic blood.

Other changes in acclimatization are less fully explained. Changes in the affinity of blood for oxygen are in some dispute among observers and are relatively small in any case. Observations of increased myoglobin in muscle are probably significant. The increased bilirubin in blood is similar to that found in other polycythemias.

It is logical that there is also acclimatization at a local cellular level probably in many tissues but most clearly demonstrated in germinal cells. Decreased fertility of humans and domestic animals brought to altitudes above 15,000 feet is a common observation. Restoration of fertility observed histologically as well as in population studies is probably one of the last manifestations of acclimatization.

The subject of *chronic altitude sickness* is of theoretical interest although it has been observed and recorded only in the high Andean plateaus above 15,000 feet. As described by Monge, it has all the chief clinical features of polycythemia vera including plethora, vascular occlusions in

various vital organs, ulcerations and bleeding in the gastrointestinal tract, sometimes cardiac failure and if untreated results in death. Its main difference from polycythemia vera is that it is completely relieved by transporting the patient to sea level. Although some of the reported cases may have had complicating cardiovascular disease of other cause, it is likely that the disease is an example of the vascular difficulties imposed by the viscous blood of polycythemia. It is of interest that in the vicuña and other animals living at high altitude, species adaptation is not by polycythemia but by increased concentration of hemoglobin in cells and by increased affinity of their hemoglobin for oxygen.

Acclimatization for high altitude aviation probably does not occur. In other words, repeated short exposures to hypoxia are not effective stimuli to adaptation. Even eight hour daily exposures cause very minor improvement in tolerance.

As mentioned briefly earlier, the effect of altitude in aircraft is peculiarly insidious, particularly on mental processes. With no real acclimatization possible, the effects of an altitude of 15,000 to 18,000 feet for example are more severe than in the mountains. Dangerous collapse is not uncommon and is well documented in aircraft misadventures as well as in experiments with low pressure chambers.

Pressurization of aircraft cabins essentially avoids high altitude exposure from aircraft travel provided ventilation is sufficient to prevent CO accumulation. Oxygen inhalation by the demand type of mask as used in some military aircraft prevents hypoxia up to altitudes of about 40,000 feet but in this range the effect of lowered barometric (and nitrogen) pressure is a major factor. At about 25,000 feet dissolved nitrogen in the blood and tissues comes out of solution causing a syndrome similar to that of decompression illness from high pressure work. (See section on Decompression Illness.) For special aviation work, pressure suits have been devised to raise the ceiling of flight in nonpressurized aircraft.

## Blast Injury

Blast injury is the term applied to the physiological disturbances and internal structural damage caused by the pressure wave from an explosion. The blast injury itself is not characterized by evidence of injury on the body surface but it frequently occurs concomitantly with other forms of trauma. In this discussion we are not concerned with the purely psychiatric syndrome which also has been labeled blast injury.

The rapidly expanding gases from an explosion generate a sharp rise in pressure in the surrounding zone of air or water. This pressure wave is then propagated in a manner analogous to the transmission of a single sound wave. When this pressure wave meets a human body it has little effect on solid organs and tissues but may cause rapid and damaging distortion of those tissues containing air such as the eardrums, the lungs and the intestinal walls. The amount of damage is related fairly closely to the maximum pressure of the wave pressures between 3 and 15 atmospheres cause detectable but not necessarily fatal injuries to the lungs in animals.

Minimum trauma in the lungs consists of petechial hemorrhages mostly on the lung surfaces between ribs. If the hemorrhages are at all extensive secondary edema occurs in the hour or two after injury and local areas of emphysema are common. In more intense blasts the hemorrhages occur more widely in the lung and involve larger vessels so that gross blood may escape into bronchi and trachea. In the intestines trauma consists similarly in mild cases of intramural hemorrhages in severe cases of rupture. The colon and lower small intestine are most often involved. Lung injuries are predominant in air explosions in water the incidence of intestinal injuries is considerably increased. Hemorrhages in the brain are caused occasionally apparently the pressure is transmitted from the great vessels in the thorax to the cerebral vessels.

The person suffering blast injury in air will usually be bowled over by the explosion and most likely rendered temporarily unconscious. When conscious he may be dazed almost surely he will have ear pain and partial or complete deafness but otherwise he may have no symptoms. If the lungs are injured he will soon complain of dyspnea and chest pain which may progress rapidly. If the damage is severe cyanosis will become apparent and blood may appear in the sputum. Severe blood loss into the lungs not infrequently leads to shock. Abdominal symptoms are rare in air blast injury and when present are found usually in association with severe lung injury. In immersion blast injury the abdominal symptoms often predominate and vary from the mild pain of a few petechial hemorrhages to the acute abdominal catastrophe of intestinal rupture.

The primary point of diagnosis lies in the recognition that internal injuries may exist without external evidence of trauma. Even if burn fractures or lacerations are present the possibility of blast injury should be kept in mind. The presence of damage to eardrums adds greatly to the suspicion of internal blast injury. Bradycardia often extreme has been frequently noted and may be a useful diagnostic sign.

Prognosis in air blast injury depends almost entirely on the extent of pulmonary damage. Grossly bloody sputum is a dire prognostic sign as is intense cyanosis or shock.

Treatment is primarily aimed at the relief of dyspnea and anoxia by the use of inhalation oxygen, tracheal aspiration and rest. Since shock if present is associated with internal blood loss whole blood transfusion is the treatment of choice. Treatment of the rarer manifestations in other organs is that of internal trauma to these organs from other cause.

## Motion Sickness

(Air Sickness Sea Sickness)

Air sickness and sea sickness may be defined as conditions due to frequently repeated oscillatory movements of the body in a ship or airplane and characterized by dizziness, nausea, vomiting, pallor and sweating.

**Etiology** In a ship the pitching, see-saw movement on a transverse axis through the center of the ship, the rolling movement on its long axis and the movement of the entire ship up and down constitute the usual motions to which a person is subjected. In airplane travel vertical accelerations and excessive rotary motions bring on the disturbance. Recent evidence indicates that the basic cause of air sickness is violent head motion which affects the fluid in the labyrinthine channels of the inner ear. Visual, psychogenic and kinesthetic factors play a subsidiary role varying with the person.

**Symptoms** The symptoms may come on without warning. A man who was previously in good spirits may suddenly become quiet and subdued. He feels nauseated and is aware of excessive salivation. Mental depression is almost constantly present. Vomiting may then take place with mild headache. Pallor and cold sweats are common. True vertigo is rare. There are no characteristic objective signs, although a drop in systolic blood pressure has been reported accompanied by tachycardia or a slow pulse rate. The nervous component in both air and sea sickness is at times important.

**Treatment** Fixing the eye on a definite object in space undoubtedly is of real help in both air sickness and sea sickness. The eye should not be allowed to shift with the position of the airplane for the earth or sky will swim past the eyes and produce dizziness or nausea in a manner comparable to the development of this condition when one whirls rapidly on a piano stool. Head rests in airplanes have significantly decreased motion sickness. When possible, travelers should place their heads firmly against the back of the seat, decreasing forward and backward movements.

Many drugs have been advocated which either act as sedatives to the entire organism or effectively suppress the parasympathetic nervous system. Hyoscine is no longer recommended since other drugs may now be used in which there is no hazard of respiratory depression from overdose.

Dramamine, 50 mg to 100 mg generally provides adequate protection for four to six hours. Bonamine is more effective and less apt to produce drowsiness. It may be administered as a 25 mg tablet at twelve hour intervals or in 50 mg dosage daily preferably about one hour before boarding the plane or ship. The syndrome of motion sickness responds better to preventive medication but the drugs listed are helpful even after the symptoms have developed.

## Electric Shock

Electric shock may result when the body becomes part of the path of flow of current between poles of different potential. Broadly speaking, alternating currents are considered much more dangerous than direct currents. Fatal shock seldom results from contact with a direct current of less than 300 volts but the danger increases as higher voltages are attained. Alternating currents of few cycles (15 to 60) may cause death in well grounded subjects even at the 110 to 115 volts commonly used for home lighting but alternating currents of high voltage if of very high frequency may be handled with relative safety. MacLachlan concluded from an analysis of 479 cases of electric shock that the severity of shock decreased or the success of resuscitative efforts increased as the potential of the circuit involved increased. The resistance offered by the body as a conductor is a factor determining the severity of shock. The resistance of dry skin is about 50,000 ohms per square centimeter, varying in different parts of the body. Moisture from sweating or wet clothing may lower the resistance to 1200 or 1500 ohms.

If skin resistance reaches 1200 ohms an alternating current of 110 volts may prove fatal. The nature of the "ground" may determine the seriousness of shock. A subject immersed in a water filled bath might be killed by a current which could be tolerated under other circumstances. The duration of contact is also of great importance since the severity of shock increases with an increase in the duration of contact. Prolonged contact with low voltages is more likely than with high voltages for in the latter case the victim often falls clear aided by violent muscular contractions.

**Etiology** The tendency of current of low voltage is to arrest the heart without affecting the respiration. Alternating currents of low tension throw the heart in fibrillation. High tension currents affect the central nervous system causing inhibition of respiration. In one the result is heart death in the other respiratory paralysis. It is inadvisable to generalize regarding the action of currents of moderate tension since many variable factors such as skin resistance, grounding, source voltage, amperage, duration of contact and kind of current determine the severity of the shock. Much remains unknown concerning the mechanism and the effects of electric shock although the studies of Hoff and Nahum and their associates have contributed greatly to knowledge in this field.

**Morbid Anatomy** Postmortem evidences of electrocution are variable. Extensive charring may mark the points of entrance and exit of the current or the burns may be slight or absent. The superficial destructive effects of direct currents are usually more extensive than those of alternating currents. The blood is often dark and is rarely coagulated. Minute hemorrhages and areas of destruction may be found in the brain and cord. Reference should be made to the detailed reports of studies of the effects of electric shock upon the nervous system published by Morrison, Weeks and Cobb.

**Symptoms** Loss of consciousness momentary or prolonged and burns of varying degree usually accompany severe electric shock. Death may be instantaneous or may result after some moments or hours. Convulsions and priapism are common. Those who recover from shock may suffer various after effects such as persistent muscular pain, fatigue, headache and nervous irritability. Progressive loss of vision with opacity of the lens has been reported. There are usually no permanent effects in those recovering from shock. Be-

cause of the tendency to electrolysis of deep tissues and to the destruction of vessel walls the possibility of delayed hemorrhage must be kept in mind in the treatment of cases involving extensive burns.

**Prognosis** In cases of cardiac failure due to ventricular fibrillation death must be expected. Respiratory paralysis often responds to artificial respiration. (In experimental animals however cardiac function has been restored after induced ventricular fibrillation. Wiggers.) Jex Blake considered death due to (1) prolonged muscular tetany resulting in asphyxia (2) ventricular fibrillation (3) respiratory failure through effects on the nervous system or (4) delayed effects of burns. To these causes Kowenhoven would add the more immediate effects of heat production and tissue coagulation.

**Treatment** When the victim is freed from the current artificial respiration is the first measure necessary in the treatment of electric shock. It should be instituted at once since a delay of even moments may result in death. Although the "back pressure arm lift" method is rapidly replacing the "prone pressure" method either may be used and should be continued until rigor mortis sets in. One patient at least was revived after 8 hours of effort. There is some evidence that the return of normal respiration is hastened by the supplementary use of oxygen inhalations. Counter shock or stimulation by mechanical means has been advocated but there is little or no reason to believe that it is of value. Different authors following the experimental work of Levy who showed that ventricular arrhythmias leading to ventricular fibrillation and death could be induced by conditions which stimulated the heart and by equivalent conditions which removed or reduced depressing influences have called attention to the often fatal consequences of administering epinephrine and other stimulating drugs in electric shock. Hoff and Nahum discovered that acetylcholine given to experimental animals protects them from ventricular fibrillation and death when they receive an electric shock of the strength which normally causes fibrillation of the ventricles. The important clinical application which is suggested by these findings is obvious. Spinal punctures as a hospital procedure in the after treatment for persistent headache or signs of cerebral pressure are of some value.

# Diseases Due to Chemical Agents

## Carbon Monoxide Poisoning

Carbon monoxide is a gas produced by the imperfect oxidation of carboniferous material and is probably the most widely distributed of toxic agents. It is slightly lighter than air, nonirritating, colorless, tasteless, and in moderate concentrations odorless. Ordinarily carbon monoxide does not appear in nature but may be encountered in the home through accidental leakage of manufactured gas from open burners and defective appliances and from incomplete combustion of various commercial gas products. It is also encountered in many industries, particularly in coal mining, in the steel industry, in gas manufacturing in processes utilizing gas heat, and in connection with the use of explosives in confined spaces. It is found in smoke in compartments which have been painted with oil paints and sealed, and in the exhaust of internal combustion engines. Many deaths have occurred in closed garages from motor exhaust gas, and manufactured gas long has been used in suicide. Coal gas contains about 16 per cent carbon monoxide, blast furnace stack gas 28 per cent, mine air after dust explosions 1 to 8 per cent, and the exhaust from automobile motors about 7 per cent.

**Incidence.** Without doubt countless persons are daily affected to some degree by carbon monoxide. There is a striking variation in individual susceptibility, but no evident racial or sex predisposition. Children are believed to be more susceptible than adults, possibly because of their relatively greater respiratory exchange, body weight considered. Persons with cardiorespiratory disease are handicapped when exposed to

carbon monoxide, and the preexistence of certain nervous disorders may in persons poisoned result in aggravation of the nervous manifestations. Some degree of acclimatization to carbon monoxide develops among those continually or frequently exposed to the gas, and is shown in the lessening of symptoms during successive exposures to the same concentrations. The possible explanation of this acclimatization is suggested by Killick as due to (1) a selective activity of the alveolar membrane producing either a secretion of oxygen from the alveoli into the blood, or an excretion of carbon monoxide from the blood into the alveoli, or (2) removal of carbon monoxide from the blood by oxidative or other processes in the tissues.

**Etiology.** Carbon monoxide has an affinity for hemoglobin two hundred to three hundred times that of oxygen. The reaction, however, is reversible and depends upon the relative tensions of carbon monoxide and oxygen in the alveolar air. The gas is harmful in that it produces anoxemia. Death is due to respiratory failure. Though the problem has occasioned much study, it has not been demonstrated that carbon monoxide is of itself specifically toxic. Haldane suggested that it may poison a catalyst of oxidation.

Poisoning depends not only upon the carbon monoxide content of inspired air, but also upon the duration of exposure to the gas. Particularly when exposed to moderate concentrations, the blood does not attain the full saturation theoretically possible. The maximum allowable concentration of carbon monoxide recommended by the American Standards Association is 100 parts per 1,000,000 parts of air by volume, with atmospheric oxygen not below 19 per

cent by volume for exposures not exceeding a total of eight hours daily and 400 parts per 1 000 000 parts of air by volume for exposures not exceeding a total of one hour daily

**Morbid Anatomy** In the postmortem examination of victims of carbon monoxide poisoning there is often noted a bright cherry color of the blood. Lining membranes are exceptionally red or show ecchymoses. Particularly important are pathological changes in the brain characterized by hyperemia, edema, hemorrhage and diffuse degeneration. Softening in the lenticular nucleus is regarded as the most typical lesion in carbon monoxide poisoning. Yant and others found in dogs that the cells of the cortex, the corpus striatum, the dorsal motor nucleus of the vagus and the dorsal sensory areas of the medulla were especially involved. Neurons were severely damaged showing disruption, marked chromatolysis and other degenerative effects. Though still a matter of some dispute the effects of carbon monoxide upon the nervous system are generally considered to be due essentially to asphyxia and not to immediate toxic action.

**Symptoms** It has been observed by Sayers and others that the character and severity of symptoms under any degree of blood saturation depended largely upon the duration of exposure and the accompanying muscular activity and further that with a blood concentration resulting from long exposure to a low atmospheric concentration there were noted more severe symptoms and after effects than with a similar blood concentration resulting from a short exposure to a richer carbon monoxide mixture. In general a concentration of 0.06 per cent or 6 parts of carbon monoxide in 10 000 parts of air produces headache within an hour and unconsciousness in two hours while 0.1 per cent carbon monoxide or 10 parts in 10 000 produces unconsciousness in a little more than an hour and may prove fatal in four hours.

Carbon monoxide may kill with great suddenness. Victims of mine dust explosions have been found in attitudes indicating that there was no warning of impending danger. Though headache is usually the first symptom the onset may be insidious. There have been many cases displaying a progressive muscular weakness without loss of consciousness but with disturbances of memory the victim passing into a rather insouciant oblivion from which he may emerge promptly or from which he may pass into full coma.

The after effects in those recovering from acute poisoning are extremely varied. Headache, vertigo, muscular weakness and nausea are common. More rarely encountered are serious disturbances of memory, vision, hearing and speech or psychoses, neuritis and paralysis. Cerebral hemorrhage has been observed some days after apparent recovery. A moderate polycythemia may persist for some time after all carbon monoxide has disappeared from the blood.

**Chronic poisoning** by carbon monoxide is believed by many authors to be a clinical entity. The alleged effects produced by repeated exposures to low concentrations of carbon monoxide are headache, malaise and an ill defined debility. However, carbon monoxide is neither cumulative nor proved to be toxic and other causes should be sought for these and other subjective symptoms which persist long after the exposures to carbon monoxide have ceased.

**Diagnosis** Absolute diagnosis is dependent upon the identification of carbon monoxide hemoglobin. Hunter describes a simple test which may be used to prove the presence of carbon monoxide in the blood. A greatly diluted solution of the suspected sample is compared with that of normal blood similarly diluted. The latter is yellow, whereas blood containing even a very small trace of carboxyhemoglobin is pink. When the proportion of carbon monoxide in the blood is more than 40 per cent of saturation, spectroscopic examination affords a confirmatory test. Carbon monoxide indicators are now available on the market which indicate by direct reading of a meter the percentage of carbon monoxide present. One of these is said to be sensitive to 0.005 per cent.

**Treatment** Emergency treatment requires immediate artificial respiration if breathing has ceased, preferably by the back pressure arm lift method. It may be used advantageously for a short while even though the victim is breathing if asphyxia is marked. The use when possible of an inhalator for the administration of oxygen is most desirable. The inhalation of pure oxygen greatly accelerates the release of carbon monoxide, freeing it about four or five times as rapidly as does air.

Patients should not be permitted any physical exertion and should be kept warm. Seriously poisoned patients after receiving emergency treatment may well be placed under observation in a hospital. Medication and blood transfusions are rarely if ever indicated.

## Silo Filler's Disease

In 1914 Hayhurst and Scott reported the death of four persons occurring apparently within about five minutes after their entering a partly filled silo. Chemical analyses of the silo gases indicated an excess of 38 per cent carbon dioxide gas. Under ordinary conditions about 0.03 per cent of the gas is found in the air. Since that time numerous deaths—all during the autumn months—have been reported attributed to asphyxiation by carbon dioxide given off from fermenting ensilage.

Another hazard in silo filling frequently referred to as a form of silo disease results from exposure to the oxides of nitrogen present in recently filled silos. In 1958 Lowry and Schuman reported findings of *bronchiolitis obliterans* at autopsy in two persons who died after exposure. Other similar cases have been recently reported. So far there is no specific treatment for the resulting lung pathology. The maximal permissible safe concentration for the oxides of nitrogen is 40 parts per 1 000 000 for an eight hour daily exposure.

Prevention depends upon a wider recognition of the hazards involved and adequate ventilation. People and animals should not be permitted to enter spaces adjoining a silo until ten days after the filling operations are completed.

## Carbon Tetrachloride Poisoning

**Definition** Carbon tetrachloride (tetra chloromethane) poisoning may be defined as an acute subacute or chronic intoxication caused by carbon tetrachloride or its vapor. It is characterized clinically by acute abdominal symptoms or pulmonary involvement as well as by serious injury to the liver and kidneys. The clinical picture in some instances is dominated by pulmonary and renal injury either alone or combined with hepatic effects not evident in others. Signs of liver damage with evident jaundice and hepatic tenderness are outstanding. In some persons gastrointestinal symptoms may be so severe as to lead to an early diagnosis of food poisoning or even of acute appendicitis. A defatting of the skin with a resulting dermatitis may follow contact with carbon tetrachloride.

**Etiology** Carbon tetrachloride is the most widely used of the halogenated hydrocarbon group of organic solvents. It is encountered industrially as an extractant for fats and oils as a solvent in rubber cements, textile soaps and other combinations and as a cleaning fluid and in fire extinguishers. It is used in offices and homes as a dry-cleaning and degreasing agent. Medically it is occasionally used as a vermifuge.

Carbon tetrachloride alone or mixed with other solvents has been sold under many trade names such as Carbona, Asordin, Chlorasol (25 per cent carbon tetrachloride, 75 per cent ethylene dichloride), Phoenipine, Katarine, Pyrene, Spectral, Tetra, Tetracol, Tetraform and no doubt others.

Like other volatile solvents, carbon tetrachloride exercises its effects only after absorption into the body. The severity of the effects is generally proportional to the quantity absorbed. Absorption may take place by inhalation of the vapor, ingestion of the liquid or through prolonged or repeated contact of the liquid with the skin and mucous membranes. The mode of entrance appears to have little or no influence on the results produced except that acute poisoning almost always follows exposure to an atmosphere highly contaminated with

vapor or to mistaken drinking of the liquid carbon tetrachloride. Elimination takes place primarily through the lungs.

The maximum acceptable concentration of carbon tetrachloride by the American Standards Association is 25 parts per 1 000 000 parts of air by volume corresponding to 157 mg per liter at 25° C and 760 mm of mercury for exposures not exceeding eight hours daily with the understanding that variations should fluctuate around 10 parts per million.

**Pathology** In fatal poisoning which may follow a single exposure to a high concentration of the vapor damage to the liver kidneys heart adrenal glands and nervous system as well as a cerebral hemorrhage and bronchopneumonia with pulmonary edema may result. Liver sections show a disseminated central necrosis with degenerative changes in the peripheral cells. Petechial hemorrhages may be found on the surfaces of the lungs. Areas of consolidation are not unusual. The kidneys may reveal a lower nephron nephrosis. Mallory describes the changes as like those in a kidney injured by transfusion crush or sulfonamides.

**Symptomatology** There is considerable variation in the signs and symptoms of carbon tetrachloride poisoning depending upon the nature of exposure. Acute intoxication results when an excessive amount of the vapor or liquid is absorbed into the body within a short period of time. The first acute reaction is similar to that to chloroform—dizziness nausea vomiting backache malaise headache giddiness and unconsciousness—but is more toxic. The narcotic effects are less marked than those of chloroform but the effects on the liver kidneys and heart are much more rapid. The effects on the heart are important in acute poisoning because in addition to acting as a heart depressant there is a tendency to cause fibrillation. Death may occur from circulatory or respiratory failure or the patient may recover within one or two days without any apparent after effects.

Subacute poisoning usually resulting from prolonged or repeated exposure to an atmosphere containing a high concentration of the vapor but insufficient to cause loss of consciousness may cause headache nausea fatigue vomiting dizziness visual disturbances subconjunctival hemorrhage coughing and bleeding from the mucous membranes. Some cases present hypertension. Acute renal damage with albumin and casts in the urine or

anuria may develop early and toxic hepatitis with a moderate degree of jaundice frequently occurs particularly in subjects who have ingested rather than inhaled carbon tetrachloride. Pulmonary complications and coma may follow within a week after exposure and in some cases end fatally in one to two weeks.

**Chronic poisoning** which is the result of daily exposures each small in itself over a longer period of time may be recognized by local symptoms of irritation of the mucous membrane of the eyes nose and upper respiratory tract. The patient in variably complains of headache sleepiness fatigue and in more advanced stages abdominal pain edema and oliguria or anuria. Jaundice may or may not be present. Affections of the central nervous system have been observed.

**Diagnosis** There may be confusion in the diagnosis of carbon tetrachloride poisoning because of the variability in its manifestations. A history of absorption of an adequate quantity of carbon tetrachloride irrespective of the portal of entrance together with the symptoms and signs of the intoxication should make the diagnosis reasonably certain. In general medical or hospital practice carbon tetrachloride poisoning is encountered most frequently after inhalation or skin contact with cleaning fluids in a closed room or after ingestion by alcoholics.

Liver function tests kidney function tests roentgen findings in the chest and electrocardiograms should be carefully evaluated. Serum bilirubin and nonprotein nitrogen are apt to be increased. Albumin and casts in the urine are found in renal involvement. There may be changes in the blood count but these do not dominate the picture as they do in poisoning by hydrocarbons of the benzene ring group or solvents.

**Roentgenographic findings in the lungs** may vary from a mild prominence of linear markings to complete consolidation of one or more lobes of the lungs.

**Prognosis** Although the fatality rate from carbon tetrachloride poisoning is low compared with the number of cases of intoxication reported there are a sufficient number of deaths to emphasize the need for precaution against carelessness in its use and inadequate safety measures. In fatal cases nearly all deaths result from kidney and liver damage and occur three to ten days after exposure. Most patients who survive the acute illness recover completely.

**Treatment** Most important in any poison

ing is the prompt separation of the victim from the offending substance. In instances in which the victim is overcome from inhalation of carbon tetrachloride vapors immediate removal to an uncontaminated area where he can rest quietly and be kept warm is imperative. If breathing has stopped artificial respiration and the administration of oxygen are indicated. Hot tea or coffee may be given as a stimulant if the patient is conscious but alcoholic stimulant or epinephrine is contraindicated in all stages of carbon tetrachloride poisoning. When carbon tetrachloride is swallowed absorption from the stomach and intestines is rapid but early lavage or induced vomiting may be helpful. This may be followed with Epsom salt (1 tablespoon) in water. All contaminated clothing should be removed and affected skin areas should be washed thoroughly with mild soap and warm water. A mild ointment containing petrolatum or lanolin may be applied to the affected skin areas. Any of the liquid carbon tetrachloride entering the eyes should be flushed out with copious quantities of water at room temperature.

In the absence of specific therapy further treatment must be largely symptomatic, varying with the individual symptoms and signs. When kidney function is impaired the treatment is that of acute urinary suppression as outlined in the section on Diseases of the Kidneys. Liver damage should be treated as described in the section on Diseases of the Liver.

**Prevention.** The measures at our disposal for the control of harmful concentrations of carbon tetrachloride as well as other solvent vapors in the plant atmosphere fall within three special fields: safety engineering and medical. Safety measures must be used against accidents or irregularities in operation. Labels on cans and drums should indicate the hazardous nature of the substance and workmen should be instructed as to the dangers. Personal protective devices such as protective clothing, goggles and respirators—the latter are only for short exposures—should be provided when necessary. Good housekeeping and sanitary facilities are essential and include segregation of processes, care of spilled solutions, receptacles for soaked rags and ample general ventilation.

## Benzene Poisoning

Benzene (benzol,  $C_6H_6$ , to be distinguished from petroleum benzene) is with disturbing frequency the cause of serious and even fatal poisoning. Benzene is obtained by the distillation of coal and the cracking of certain grades of petroleum. It is used widely in the manufacture of rubber goods and artificial and patent leather in lacquers, paints, printing processes as a solvent for fats and greases and motor fuels and for a great variety of other purposes. Commercial benzene contains a number of impurities such as thiophene and various homologues of benzene, particularly xylene and toluene. Extended investigation of the toxicity of such impurities has produced conflicting evidence, but the preponderance of opinion favors the belief that they are not responsible for the effects generally attributed to benzene.

**Etiology.** Benzene poisoning is usually caused by inhalation of its vapor, though it can be produced by skin absorption. Although individual susceptibility to benzene varies greatly for reasons not determined, the American Conference of Governmental Industrial Hygienists (1957) has adopted the threshold limit value of 25 parts benzene per 1,000,000 parts of air for the maximum average atmospheric concentration to which workers may be exposed for an eight-hour working day without injury to health.

**Morbid Anatomy.** Most striking among postmortem findings are multiple hemorrhages throughout the body, uncoagulated blood abnormalities of the bone marrow, spleen and lymph nodes, and evidences of secondary infection.

**Symptoms.** Acute poisoning may take place with great rapidity and death may ensue in a few minutes. Beginning with sudden dizziness, the victim may quickly show great muscular weakness and lapse through drowsiness into coma. Tremors

delirium or convulsions are more infrequent. There is often marked dyspnea with possibly a sense of constriction of the chest which may proceed to death from respiratory failure. The pulse is small and rapid the skin pallid or cyanotic occasionally showing ecchymoses.

*Chronic poisoning* or subacute poisoning is much more frequent and is manifested usually after days or months of exposure to benzene. The early evidences of disease are commonly rather vague such as loss of appetite and weight headache vertigo and muscular weakness. As the condition progresses pallor is marked and is associated with a true anemia. Dyspnea and air hunger may be striking. Convulsions and delirium are rare. Abdominal pain and gastrointestinal irritation with nausea and vomiting are common. Hemorrhages from the nose gums bowels kidneys and vagina as well as into the skin and mucous membranes are typical. The urine often shows evidences of nephritis with casts albumin and blood. Furunculosis may be encountered and possibly dermatitis related to skin contact with benzene.

The blood picture may vary considerably from the so called classic changes. Leukopenia neutropenia thrombocytopenia hypochromia eosinophilia and anemia may or may not be present. The bone marrow may be aplastic or it may be affected or hyperplastic or leukemic. Resistance to infection is lowered.

**Diagnosis** The use of arbitrary criteria for diagnosis is not advocated. The diagnosis cannot be made upon blood findings alone since these may simulate various blood dyscrasias. The blood picture of agranulocytosis may be similar to that produced by benzene and the other well known causes of leukopenia. A history of exposure to benzol should be the determining factor in the diagnosis of benzene poisoning. The aromatic hydrocarbon detector developed by the Mine Safety Appliance Company is a useful apparatus for the field determination of benzene vapor.

**Prognosis** Many seriously poisoned patients have died after several days or weeks others have recovered after prolonged illness. The mortality among severe cases has in the past been about 50 per cent.

**Treatment** Acute poisoning requires repeated washing of the stomach followed by the administration of 2 to 3 tablespoons of magnesium sulfate in 250 ml of water. In instances of respiratory failure prompt artificial respiration is indicated. The use of oxygen administered with an inhalator

is advised. Serious blood destruction and hemorrhage are best treated by blood transfusion possibly repeated many times. The blood picture should be observed frequently. Preparations of liver have been used to advantage. Lane reports that corticotropin has been used successfully in some cases of aplastic anemia due to benzene. Other treatment is symptomatic. Because of lowered resistance to infection complications may appear such as pneumonia bronchitis and cystitis.

Prophylaxis involves careful control of industrial processes in which benzene is used adequate ventilation the selection of healthy persons as workers with benzene and the periodic examination of persons exposed to the end that those even slightly affected may be removed.

## Beryllium Poisoning

### (Berylliosis)

**Definition** Beryllium poisoning or berylliosis is a general term which includes all those acute and chronic manifestations resulting from exposure to the fumes and dusts of beryllium salts and alloys. In human beings the major clinical forms have been characterized chiefly by acute pneumonitis and chronic pulmonary granulomatosis. Surface contact with the material may cause lesions such as conjunctivitis corneal ulcer dermatitis on the hands arms face and neck skin ulcer or granuloma and subcutaneous granuloma.

**Pathology** In the acute form of the disease the lungs present a picture of bilateral diffuse pneumonitis with pronounced intra-alveolar and interstitial exudates. The air

spaces are filled with plasma cells lymphocytes and mononuclear phagocytes at tended occasionally with edema and hemorrhagic extravasation. These may infiltrate the smaller blood vessels and bronchioles. There is an early proliferation of fibroblasts. Unlike cases of acute chemical pneumonitis from other causes polymorphonuclear leukocytes are relatively few.

The chronic form of the disease is characterized by marked emphysema and a bilateral diffuse granular or nodular infiltration scattered through the lung fields. The normal structure of the lungs may be altered and is often obliterated by these changes.

The nodular granulomatous lesions are located in the thickened walls of the alveoli and in the fibrous tissue around the bronchi and blood vessels. The central core of the lesions consists of fibrinoid material lymphocytes plasma cells large mononuclear phagocytes and giant cells of the Langhans type. The peripheral zone consists of fibrous tissue infiltrated with small round cells. Giant cells may or may not be present. Conchoidal bodies are present in most cases.

The mediastinal and axillary lymph nodes are infiltrated in some instances by a similar granulomatous process. Liver involvement also has been observed. The skin and subcutaneous tissues may be the sites of granulomas following accidental introduction of beryllium compounds.

**Morbid Physiology.** The extensive changes in the parenchymal lung tissue and associated thickening of the walls of the alveoli interfere with the exchange of gases in the lungs. Alveolar capillary block develops with uniform reduction in lung volume hyperventilation well maintained maximum breathing capacity arterial oxygen unsaturation (particularly on exercise) and normal or even low carbon dioxide levels. The anoxemia is due to impaired diffusing capacity of the lungs for oxygen.

**Symptoms.** The acute form of the disease develops usually after a relatively short period of exposure. The symptoms may appear insidiously or suddenly beginning with an acute irritation of the upper respiratory tract cough which is often non-productive dyspnea substernal discomfort or pain anorexia weakness and weight loss. The objective signs reveal a thin anxious person with little or no elevation in body temperature. There is usually some swelling and redness of the mucous membranes of the nose and throat. Cyanosis is evident in severe cases. Rales may be de-

tected in both lung fields. The illness may subside within a few weeks or extend into several months.

The symptoms and signs in chronic cases appear insidiously and include exertional dyspnea weakness irritative cough and weight loss. The onset of symptoms may be delayed for periods of several weeks to five or six years following termination of exposure. As the disease progresses the symptoms become more localized and intense. There is a progressive loss in weight and variable degrees of respiratory distress. The patient appears nervous and complains of pain in the chest and abdomen weakness and fatigability. Cyanosis and clubbing of the nails may be present. The pulse rate is usually increased and definitely accelerated in cases of cyanosis. The blood pressure usually drops during the course of the disease. Rales and loss of resonance have been observed. Reduction in vital capacity may become marked as the disease progresses. The duration of the disease is prolonged usually for a period of several months.

**Diagnosis.** The diagnosis is made after a careful evaluation of the occupational history type of onset and clinical manifestations roentgenographic characteristics and chemical findings of beryllium in tissues obtained by skin biopsy or in the urine.

The occupational history should include all occupations in which the patient has been engaged and the duration of employment in each as well as all obtainable information on the amount and kind of dust and fumes to which he has been exposed and the extent to which protective devices were used. The inhalation of beryllium dust after breaking fluorescent lamps may occur and this possibility should be inquired into when there is a history of exposure prior to 1949. Beryllium phosphors have not been used in the manufacture of fluorescent bulbs since that date.

In roentgenographs of the lungs in acute pneumonitis a diffuse haziness may be noted two to three weeks after the early symptoms of the disease. There is usually prominence of the peribronchial markings and irregular opaque shadows suggestive of pulmonary edema followed by discrete small or large conglomerate nodules scattered throughout both lung fields. Clearing of lung fields occurs usually after one to four months.

The roentgenographic changes in the chronic disease are characterized by small discrete stippling and fine nodulations scattered throughout both lung fields re-

sembling the shadows cast in miliary tuberculosis in sarcoidosis and in early uncomplicated silicosis. As the disease progresses confluent nodular shadows with emphysematous spaces between appear throughout both lung fields. There may be an accompanying enlargement of the hilar lymph nodes.

**Prognosis.** The course and prognosis of beryllium poisoning depend largely upon the form of the disease. The mortality rate is low in the acute form. Only occasionally has death occurred early in its course. The transition from acute pneumonitis to chronic pulmonary granulomatosis has so far rarely been observed. Machle and his co-workers, however, report that an attack of acute disease has been followed two years later by the onset of chronic berylliosis and gradations of intermediate degree occur.

The chronic course of the disease is one of protracted convalescence in a few and gradual progression and eventually death in many. Machle reports a fatality rate of 20 per cent in his series of cases. Cutaneous lesions do not readily heal unless all particles of the beryllium material are removed and granulomas of the skin are excised.

**Treatment.** In the absence of specific therapy in the acute and chronic pulmonary forms of the disease the treatment must be largely supportive. Enforced bed rest in early and severe cases is indicated. Oxygen therapy is required to overcome cyanosis and dyspnea and to prolong life. Cortisone and ACTH have been shown to induce striking improvement in pulmonary function with marked clinical improvement in a number of patients with pulmonary granulomatosis. Antibiotics may be of value in preventing secondary infections.

Dermatitis and conjunctivitis, although severe at times, tend to clear up after removal from work. The application of a mild antipruritic or antihistaminic ointment may aid in the treatment of affected skin areas and a soothing antibiotic ophthalmic ointment may be applied in cases of conjunctivitis. Cutaneous ulcers are best treated by scraping away the base of the ulcer with a curet. Cutaneous and subcutaneous granulomas should be widely excised.

**Prevention.** Prevention consists in both medical and engineering control. A periodic checking of workers possibly exposed to beryllium containing fumes and dusts is a valuable health measure in detecting early cases. A monthly check of each worker's body weight for evidence of persistent

loss and interrogation as to symptoms such as cough, anorexia and fatigue is desirable. When suspicion points to possible disease of the respiratory system a roentgenogram of the chest should be made. All workers incurring breaks in the skin should be required to seek immediate treatment so that the medical attendant can remove all particles of beryllium compounds in the wound.

Good engineering practice consists in meticulous housekeeping and systematic determinations of the beryllium content of air at breathing levels of the workers. Until safe limits of concentrations are determined every effort should be made through engineering control methods to prevent beryllium containing fumes or dusts from escaping into the atmosphere.

## Mercury Poisoning

Mercury has long been used in the arts and in medicine. Paracelsus (1493-1541) advocated its use for the treatment of syphilis.

### ACUTE POISONING

**Etiology.** Acute poisoning is usually caused by ingestion of bichloride of mercury accidentally or with suicidal intent. The absorption of mercury administered therapeutically by mouth, injection, inunction or in vaginal douches may produce a mild acute or subacute poisoning as does rarely an industrial exposure to massive doses of mercury vapor. Ingestion of 0.1 gm. of mercuric chloride may result in acute poisoning although usually 1 gm. or more is required to render the condition serious. Mercury is quickly absorbed from the stomach and after brief storage in the liver is widely distributed.

**Morbid Anatomy** In patients dying within 24 hours after ingestion of mercury there is observed marked gastritis and possibly some nephritis. Patients dying within two to seven days after ingestion show a necrotic nephrosis and marked colitis. Those dying after one week show a tendency toward healing of the gastric and renal lesions but a severe gangrenous colitis.

**Symptoms** The onset is usually rapid within a few minutes after ingestion abdominal pain develops especially in the epigastrium. This is fortunately in most cases associated with vomiting and rejection of part of the ingested poison. There is a metallic taste and often a marked stomatitis and congestion or even ulceration of the pharynx and esophagus. The vomitus may early contain blood streaked mucus. Stools are loose and bloody. There may be prompt collapse and in exceptional cases delirium and convulsions. Examination of the blood during the first few days shows blood nitrogen increased, the blood chlorides reduced and the alkali reserve lowered. When the intoxication is not promptly fatal signs of gastrointestinal inflammation and striking evidence of injury to the kidneys usually continue. Albumin casts and blood appear in the urine a few hours after ingestion of the poison and gradual suppression of the urine and anuria may be noted.

**Diagnosis** It is important to ascertain with certainty that mercury has been ingested. Some of the new methods for the determination of mercury are the electrolytic dithizone selenium sulfide spectrographic and photoelectric. Spectroanalysis has become a valuable diagnostic aid. Small amounts of mercury have been found in the urine and stools of apparently normal healthy persons.

**Prognosis** If mercurial salts are vomited within fifteen minutes of ingestion the patient usually recovers. The frequent estimation of blood nonprotein nitrogen is of aid in prognosis. The majority of deaths occur within the first two or three days. The mortality among proved cases may run over 40 per cent though with prompt and thorough treatment in hospital it should be less than 10 per cent. If death is not caused by shock or severe gastroenteritis it is usually attributable to kidney damage.

**Treatment** Emergency treatment may include induced emesis and gastric lavage or treatment of shock. The treatment described by Weiss is devised to overcome the effects produced by the poison rather than

to provide an antidote to mercury. It may be outlined as follows:

The stomach is immediately washed with a saturated solution of sodium bicarbonate the operation being continued until the washings are clear. At least 2 liters of the solution should be used.

Lavage with 250 ml of a 5 per cent solution of sodium formaldehyde sulfoxylate has been recommended particularly in cases seen early. Before withdrawing the stomach tube 6 ounces of a saturated solution of magnesium sulfate are administered. A soap-suds enema is then given.

From the onset a beverage made by dissolving 4 gm (1 teaspoonful) of potassium bitartrate and 1/2 gm (1/2 teaspoonful) of sodium citrate in a glass of water orangeade or lemonade is to be administered six to eight times daily. Weiss has seldom used rectal irrigation or hot packs. He permits a liberal diet after diarrhea ceases.

Dimercaprol (BAL) has also been used with success in mercury poisoning. The initial dose should be 5 mg per kg (approximately 300 mg) intramuscularly followed in one or two hours by a dose of 2.5 mg per kg. After a lapse of two to four hours a second dose of 2.5 mg per kg should be given within the first twelve hours of therapy. On the second day two 2.5 mg per kg doses may be administered. It should be emphasized that the successful treatment of arsenic or mercury poisoning with dimercaprol depends on the institution of treatment at the earliest possible moment before irreparable tissue damage has occurred and on the use of adequate amounts of dimercaprol at frequent intervals.

Renal damage with suppression of urine is usually a major problem in acute mercury poisoning. For management of urinary suppression see page 1064.

#### SUBACUTE POISONING

Subacute poisoning is ordinarily caused by the excessive therapeutic use of mercury. The common symptoms—salivation, gingivitis and diarrhea—subside upon withdrawal of the drug.

#### INDUSTRIAL POISONING

Industrial mercury poisoning is almost invariably a chronic intoxication resulting from the inhalation of volatilized mercury for a long period. One milligram of mercury per 10 cubic meters of air has been accepted by the American Standards Association as the maximum allowable concentration for work places. Dublin and Vane list about 100 occupations in which mercury may be a hazard. The most hazardous trades are the production of mercury and its derivatives, the manufacture of scientific apparatus (thermometers and barometers) the extraction of gold and silver

by amalgamation the application of anti fouling plastic paint for the protection of hulls of warships against the growth of aquatic life and the preparation and handling of the fulminate of mercury as a detonator of explosives Since the recent discovery of a substitute for mercury in the treatment of fur certain states by agreement with the manufacturers of felt hats have issued regulations prohibiting the use of mercurial carot in the preparation of hatters fur or the use of mercurial carotated hatters fur in the manufacture of hats

**Symptoms** Chronic mercurialism has various manifestations not all of which may be observed in any one case The most typical symptoms are included in the first three of the following groups

1 *Stomatitis salivation* a metallic taste reddish brown discoloration of the buccal mucosa gingivitis loosening of the teeth and occasionally a marking of the gums similar to the lead line

2 *Erethismus mercurialis* a peculiar psychic disturbance characterized by ready excitability and a strange shyness in the presence of strangers insomnia headache vertigo mental depression and dullness and rarely hallucinations

3 *Tremors* of the orbit lips tongue fingers and limbs These are usually moderately fine at first but at intervals become a coarse jerking They may become severe and in rare instances involve contractions of the limbs of such violence as to require restraint The tremor is intentional and subsides during rest Under observation it may increase and diminish rhythmically recurring When it is marked the patient may require assistance in eating and in other activities Weakness of both the flexor and extensor muscles of the hand and forearm has been reported but marked paresis is rarely if indeed ever caused by mercury Polyneuritis is said to result occasionally from exposure to mercury No ataxia occurs and reflexes are not notably affected

4 *Albuminuria and High Blood Pressure* While the severe nephritis associated with acute mercurial poisoning is not associated with the chronic type these symptoms appear with such frequency as to warrant the belief that the kidneys are usually involved in chronic poisoning

5 *Loss of appetite indigestion and diarrhea* are occasionally observed There is loss of weight in severe cases The blood is normal except for a moderate secondary anemia

6 *Dermatitis* characterized by erythema

and desquamation is not uncommonly produced by contact with mercuric chloride or even by ingestion of mercury In susceptible persons fulminate of mercury produces severe dermatitis Punched out and penetrating ulcers may develop about the fingernails and knuckles The conjunctivas and the mucous membranes of the mouth nose and larynx are often affected

**Prognosis** There is apparently no acquired immunity to mercury The severity of symptoms is usually determined by the length and degree of exposure to the poison Though most severe symptoms tend to decrease when the subject is removed from contact with mercury such manifestations as erethism and tremor may persist for a long time

**Treatment** should eliminate the metal through the bowels kidneys and skin In acute mercury poisoning BAL has been effective For the dosage of BAL the reader is referred to the section on Arsenic Poisoning

Mercury dermatitis may be prevented and to some degree relieved by application of a 10 per cent solution of sodium hyposulfite A 2 per cent solution may be used as a wash for conjunctivitis

## Arsenic Poisoning

Arsenic poisoning is usually the result of exposure to one of the oxides of arsenic such as arsenous acid ( $AsO_3$ ) or to arsenical salts such as emerald green (acetoarsenite of copper) or lead arsenate Arsenic

uretted hydrogen (arsine  $\text{AsH}_3$ ) is highly toxic but produces effects different from those of arsenic salts

**Incidence** Most industrial arsenic poisoning is seen in workmen engaged in extracting white arsenic ( $\text{As}_2\text{O}_3$ ) from cobalt and arsenical pyrites in chemical works glass making and cadmium plating in agricultural spraying and dusting in the use of sheep dip or in handling skins treated with arsenic. Poisoning has been reported from the use of the organic arsenic compounds from fruit sprayed with arsenic and from certain cosmetics and proprietary remedies

Arsine is produced when an acid and a metal either or both containing arsenic are brought into contact with a resulting liberation of nascent hydrogen which combines with arsenic to form the toxic gas. Poisoning has occurred in chemical and galvanizing works in submarines because of arsenic in storage battery plates or acid on ships carrying ferrosilicon which in contact with air and moisture tends to decompose and liberate arsine and in the preparation of hydrogen for balloon inflation

**Etiology** Arsenic oxide and the salts are local irritants to the skin and the mucous membranes of the mouth and respiratory passages. Inhalation or ingestion of them produces local and systemic changes. Acute poisoning is usually due to the use of arsenic with suicidal intent. One grain (65 mg) of white arsenic has proved fatal. Though the normal therapeutic dose of this substance is 2 mg the "arsenic eaters" of Styria can safely take over 400 mg twice a week

Arsine is primarily a hemolytic agent. The inhalation of the gas over a period of several hours in a concentration of 30 parts per 1 000 000 will produce poisoning and the lethal dose as variously stated ranges from 100 mg to over 500 mg. There is apparently marked individual susceptibility

**Morbid Anatomy** Delepine reported that after poisoning by arsenic trichloride there is found granulo-fatty degeneration of the heart, liver, kidneys, pancreas and gastric and duodenal glands. After death from poisoning by arsine the liver has been found to be large and edematous with some evidence of fatty degeneration, the kidneys large and the renal epithelium degenerated and necrotic. Ecker found significant alterations in the nervous system marked by alterations in the ganglion cells and by regions of perivascular necrosis

**Symptoms** Arsenic oxides or salts as

dusts produce superficially a dermatitis or even ulceration about folds of skin as in the axillae or about the scrotum. Increased pigmentation may be noted about the axillae, the nipples, the eyelids and on the neck. Keratosis of the palms and soles may develop after prolonged ingestion of arsenic and skin cancer has been reported to follow the use of the drug. The causal relation of arsenic to skin cancer is much disputed. The septum of the nose in some cases is perforated. Other symptoms are edema of the lids, coryza, pharyngitis and laryngitis. With more serious poisoning vomiting, abdominal pain and diarrhea may be marked. A peripheral neuritis with pronounced paresthesia is moderately common. Paralysis similar to that produced by lead may result from the absorption of arsenic, the legs being more notably affected than the arms. Tendon reflexes are diminished or lost. Diffuse cerebral symptoms such as headache, vertigo, fatigue, drowsiness and impairment of mental activity may result from chronic absorption

Poisoning by arsine is manifested usually three to six hours after the gas is inhaled by malaise, vertigo, weakness, headache, nausea and vomiting. There may be abdominal pain and diarrhea. A few hours later hemoglobinuria or hematuria and albuminuria are noted. The pulse may become rapid and feeble and the respiration increased. Within a day or two jaundice and a coppery cyanosis may be observed. Oliguria may develop. The red blood cells and hemoglobin are much reduced. In very severe cases there is a high color index and evidence of extreme blood destruction as well as of regeneration. The leukocytes are ordinarily not involved though in some cases there is a slight leukocytosis. There develops rarely after several weeks a transitory toxic polyneuritis with pain or anesthesia but no motor involvement

**Diagnosis** of arsenic poisoning is facilitated by careful inquiry into the nature of the patient's work and by chemical analysis of the urine, hair and nails. In connection with such analyses it should be noted that "normal" arsenic frequently has been found in the hair, nails and excreta of persons not known to be exposed to arsenic

**Prognosis** Industrial poisoning by arsenical oxides or salts is rarely fatal. Manifestations of the disease may persist for weeks or months. Poisoning by arsine if severe is usually fatal within about a week, death being due essentially to blood destruction

The mortality is approximately 30 per cent. Serious damage to the kidneys is almost inevitable and impaired renal function complicates recovery. Convalescence is slow.

**Treatment** In acute cases of arsenic poisoning remove material promptly by gastric lavage using warm water or a 1 per cent solution of thiosulfate. The administration of absorbent charcoal and of cathartics has been suggested. Also the administration of BAL (British anti-lewisite antidote to the arsenical blister gases) may be helpful. It has been suggested that 3 mg of BAL or dimercaprol per kg or a 10 per cent solution in oil be given intramuscularly every four hours for the first two days, four injections on the third day and injections twice daily thereafter for ten days or until complete recovery. Subcutaneous injections of morphine (15 mg) may be necessary to relieve pain. Dehydration may be treated by intravenous infusion of 5 per cent glucose.

In chronic poisoning the promotion of elimination through the kidneys and bowels is recommended.

In poisoning by arsine oxygen should be promptly administered and the inhalations prolonged. Transfusion may be necessary. In the few cases of arsine poisoning in which BAL was given the results proved generally unsatisfactory. Pinto and others found that it neither stopped nor prevented the destruction of red cells.

### Metal Fume Fever

It was generally believed by earlier observers that the syndrome known as metal fume fever as well as so-called smelter shakes, brass founders' ague, zinc chills and brass poisoning was due to zinc inhaled as a metal oxide fume. The chief industries involved were brass or bronze

foundries, zinc ore smelters and those engaged in welding zinc and its alloys in brazing metals and metallizing with zinc. Later studies have shown that the fumes of other metallic oxides, antimony, arsenic, manganese, lead, copper, beryllium, magnesium and probably others will produce similar episodes of chills and fever.

The symptoms usually occur several hours after exposure and are aggravated by chilling of the body. The patient may complain of dryness of the throat, some tightness in the chest followed by a dry cough and occasionally nausea and vomiting. The fever may rise to 102° F, sometimes higher. The patient usually recovers on the day following the chill. No fatalities have been reported.

Prevention depends upon adequate engineering and medical programs. During an eight-hour day exposure should not exceed 15 mg per cubic meter of air. Suitable exhaust ventilation of the work area is essential.

### Lead Poisoning

**Definition** Lead poisoning is a systemic intoxication which may occur when the concentration of lead within the tissues reaches or exceeds a certain critical range. The intoxication, often spoken of as chronic, largely because of the length of time which may be required under given conditions of exposure and absorption for the concentration of lead in the tissues to reach the critical range, occurs usually as an acute episode of illness of fairly sudden onset. Such illness does not ensue necessarily when the critical concentration of lead in the tissues has been reached or exceeded. The illness is initiated by obscure factors which effectuate the toxic reaction.

**Etiology** Lead poisoning in the adult in the United States is essentially occupational in origin. Occasional cases are seen among persons who have been using water conveyed from a spring or well through lead pipes to a house in a rural area.

Rarely poisoning has resulted from ingestion of lead compounds in solution or in the form of paste or powder and from the absorption of lead from fragmented lead shot or bullets when these have been lodged within a joint where the combination of a fairly extensive surface mechanical erosion and local tissue reaction (usually in association with infection) has accelerated greatly the absorptive process. As a rule shot or bullets merely embedded in the tissue or encapsulated are inert and harmless.

Occupational lead poisoning occurs in association with a variety of routine procedures in which metallic lead alloys containing lead in significant concentration and other compounds of lead (such as paints of high or intermediate lead content on metallic or wooden surfaces) are heated to temperatures sufficiently high to produce lead fume or lead vapor (temperatures above 1000° C in the case of metallic lead). The heat may be applied to a mass of metal as in a furnace or melting pot or locally as by a blowtorch, an electric arc or an oxyacetylene burner. Procedures of this type result in contamination of the atmosphere of workrooms with finely divided lead or its compounds and when the concentration of respirable lead or lead compounds in the atmosphere breathed regularly or frequently exceeds 0.2 mg per cubic meter for months or years cases of lead poisoning occur.

Other industrial operations of a wide variety *e.g.* spraying, stirring, skimming, grinding, scraping, abrading, conveying and shoveling are concerned at some stage with metallic lead or lead compounds in a physical state that is conducive to the dispersion of fine particles of mist or dust into the air and to the rapid or gradual settling out of all but the finely dispersed particles upon flat surfaces within the vicinity of the operations. The contaminated air is a source of respiratory exposure to all unprotected persons in the area involved and the settled dusts constitute a source of further contamination of the atmosphere whenever mechanical procedures or air currents redisperse them.

Hazardous situations with respect to lead have been eliminated from many plants and processes in recent years and other unrecognized hazards have been introduced so that no industry *per se* is either dangerous or free of danger.

Lead and its inorganic compounds are absorbed into the body by way of the respiratory and alimentary tracts. None of

the inorganic compounds is absorbed to any practically important extent through either the unbroken or abraded skin. Certain oil soluble organic compounds of lead on the contrary are readily absorbed through the unbroken skin. Of these only tetraethyl lead has any importance in present-day industry and its only significance as a source of cases of lead poisoning arises in connection with the manufacture of tetraethyl lead and in the handling of mixtures or solutions in which tetraethyl lead is present in high concentration. Commercial leaded gasoline in which only minute concentrations of tetraethyl lead are found is not a source of tetraethyl lead poisoning in its ordinary handling and use as motor fuel except under the peculiar conditions associated with the cleaning and repairing of large gasoline tanks in which the gasoline has been stored for considerable periods of time.

The emphasis above upon the dispersion of lead in the atmosphere and the general preoccupation of industrial hygienists with the contamination of the atmosphere with lead compounds tend to minimize the importance of the absorption of lead from the alimentary tract. However lead poisoning can result from alimentary absorption alone and is the usual mode of absorption in children. Moreover the size of the particles dispersed in the air determines to a very considerable extent the fate of lead compounds that enter the respiratory tract. Many of the particles ranging in size from somewhat more than one micron upward increasingly as they increase in size are collected in the upper respiratory tract and as great a proportion as 75 or 80 per cent of those which enter the nares may be swallowed. Inasmuch as the ingestion of one milligram of lead per day in addition to that which occurs normally in food and beverages results in the slow but progressive accumulation of lead in the body it is evident that the quantity of lead which reaches the alimentary tract in connection with respiratory exposure to lead is often a highly significant factor in the total absorption of lead under these conditions.

The absorption of toxic amounts of lead by children is usually an expression of the presence in the environment of dangerous quantities of readily accessible paint of significant lead content (in excess of 1 per cent of lead in the dried paint). The usual source of dangerous quantities of lead is found to be the painted and repainted surfaces of woodwork *e.g.* baseboards, windows and window sills, cribs, play pens,

and plaster walls. Other sources of lead poisoning in infancy and childhood have been nipple shields, small toys made of metallic lead or its alloys, cosmetic powders and hair dyes.

**Pathology and Chemistry.** After the absorption of its inorganic compounds, lead is widely distributed in the tissues of the body. Within a period of about two weeks after the absorption of a single dose of significant size, the distribution assumes a pattern in which the skeleton contains 90 per cent or more of the lead in the body, but the quantities found in the viscera at all times are appreciable, those in the liver and the blood being the largest of these. Inasmuch as the average normal adult takes in somewhat more or less than 0.4 mg of lead per average day in food, beverages and respired air, the stream of lead absorption into and through the tissues of the body is always a factor in the distribution, but the pattern of the distribution in the tissues and urine is one of the most constant and stable of normal human metabolic phenomena. When the rate of absorption of lead increases coincident with abnormal exposure, the pattern of distribution is changed but little, but the quantities involved increase in rough proportion to the rate of absorption. Under appropriate conditions of abnormal exposure, the lead content of the skeleton may come to be ten to thirty times its normal level, i.e. between 1.0 and 2.0 mg per 100 gm of fresh bone, while that of the liver is likely to be elevated tenfold or more, that in the blood eight to twentyfold, and that in the urine ten to twentyfold. It is usually impossible to establish even the approximate facts with reference to the true alimentary excretion of lead in any other than balance observations of some weeks' duration, since the large proportion of the lead ingested daily and passed unabsorbed through the tract masks that which is actually excreted from the tissues. For this reason, the alimentary excretion need not be referred to beyond stating the fact that as a true excretion, it is often negligible and is rarely more than two or three times as much per day as that excreted in the urine. Under normal circumstances, the concentration of lead in the central nervous system rarely exceeds 0.08 mg per 100 gm of fresh tissue, but in fatal encephalopathy it ranges from about two to more than five times the normal.

There are no entirely characteristic changes in the tissues in lead poisoning. A variety of gross and microscopic lesions

are found, however, in association with varying types and degrees of severity of lead poisoning. Of these, the most nearly definitive are (1) the degenerative lesions of the neuromuscular apparatus involving the extensor muscles of the extremities and the associated peripheral nerves and neurones; (2) the cerebral edema of encephalopathy with or without obvious and non-specific damage to nerve cells; (3) basophilic stippling of the erythrocytes in the peripheral blood; (4) the deposition of black lead sulfide in gingival margins that are the site of inflammatory changes; the so-called lead line, and also at times in the mucosa of the large intestine; (5) and the changes in the metaphyseal areas of the long bones of children, which are visible as linear areas of sharply increased density in roentgenograms and are demonstrable as regions of unusually dense trabeculation and tissue reaction on microscopic examination. These "lines" are not specific for lead, nor is the x-ray shadow due to the elevated concentration of lead in these areas, but to the dense local structure of the bone. While vascular injury with or without petechial or even gross hemorrhage (retinal hemorrhage for example) occurs occasionally in lead poisoning, it has no special or differentiating site or character.

Whether intoxication with lead depends upon the presence of ionic lead or an ionized radical containing lead in the affected tissue or tissues as differentiated from lead which is held in an nonionized or weakly ionized combination in the tissues, or whether some other type of biochemical mechanism is involved in the process is not known. From the aspect of chemical pathology, an inhibition of the maturation cycle of hemoglobin caused by the presence of sufficient concentrations of lead results in an increase in certain porphyrins in the circulating blood and in the urine, of which coproporphyrin III is the most significant. The appearance of coproporphyrin III in the urine in sufficiently elevated concentration is perhaps the most nearly specific of all the abnormalities associated with the absorption of dangerous quantities of lead. The finding of abnormal quantities of lead is, of course, the only truly specific bit of evidence, but is not *per se* an indication of disease.

**Symptoms and Clinical Pathology.** In the adult, the commonest expression of lead poisoning is that of acute bouts of mid-abdominal pain, which may come and go or may persist with varying intensity at

its worst causing the patient to writhe "coiled up" in a cold sweat from time to time because of acute enteric spasms. There may be little prodromal indication of illness but it usually follows in the wake of a period of increasing constipation often becoming intractable in association with loss of appetite particularly at the beginning of the day and discomfort on eating. The patient usually complains of a foul rarely metallic taste sometimes of nausea with or without vomiting and of weakness which is occasionally extreme but almost always strikingly out of proportion to his apparent strength. The disease is essentially afebrile but there may be a mild elevation of temperature when bouts of colic are severe. There is pallor and although the inevitable loss of weight may be mild the patient appears debilitated. In some patients constipation and other digestive disturbances constitute the chief complaints and they are worn down by lack of sleep and weakness at least in part because of reduced food intake.

In another form of the disease the complaints are referable chiefly to the neuromuscular system with the pain of muscular hypertonus in the legs especially the calves and weakness or paralysis of the extensor muscles of the arms particularly of the forearms or hands. The latter is rarely the first manifestation of the disease being usually an expression of fairly prolonged exposure to highly hazardous occupational conditions. It is also common to find that the patient who is suffering from this form of lead poisoning has had one or several previous bouts of colic.

The cerebral manifestations of the disease develop suddenly—in adults usually as a result of severe occupational exposure especially to lead fumes. The onset may be announced by a convulsion or the patient may develop a severe headache and become confused, disoriented and negativistic. This condition may progress to a state of unresponsiveness to stimuli which may persist for some days with little change or may go on into deep coma. On the other hand the initial cerebral disturbance may clear abruptly or in a few days leaving little more evidence of cerebral involvement than that associated with a bad "hangover."

The two expressions of lead encephalopathy referred to above so different in their duration and apparent significance are probably differently mediated toxic effects of lead although the mechanisms involved are still conjectural. The form of

encephalopathy seen in infancy and childhood bears more resemblance to the severe than to the mild forms of adult encephalopathy especially in respect to its poor prognosis. Its onset is usually characterized by convulsive seizures and from its onset until shortly before a fatal termination its manifestations are more those of meningeal irritation and cerebral excitation than of depression. Like adults children show evidence of lead intoxication other than encephalopathy. The milder forms of the disease in children appear to occur with less relative frequency than the severe form but this may be more apparent than real.

Tetraethyl lead poisoning deserves special consideration because it is always primarily an acute intoxication of the central nervous system. When tetraethyl lead has been absorbed into the body in sufficient concentration the response is always the same in type with some variation in degree. This intoxication appears as a fairly characteristic mental disturbance which in the more severe cases develops in intensity with somatic manifestations of nervous excitation until the cerebral mechanisms mental and motor alike come to be involved in an outburst of activity of manic intensity. Yet when the patient survives this storm he returns ultimately to a normal state without permanent sequelae. Fatal encephalopathy due to tetraethyl lead like the encephalopathy of infancy and childhood is associated with highly abnormal and apparently definitive concentrations of lead in the brain. In view of the lack of sequelae it appears that the disorder in the brain is primarily functional and is mediated by this chemical agent.

**Diagnosis** The diagnosis of lead poisoning is made on the basis of characteristic symptoms and signs or those compatible with lead intoxication together with reliable evidence of the absorption of toxic quantities of lead and in the absence of other disease processes giving an alternative basis for the disease picture. *The history of exposure is but a clue to be investigated and discarded or substantiated as facts are gathered by more appropriate methods.*

Because the symptoms of lead intoxication are likely to be more striking than the physical signs the former must be considered with great care both as to their meaning and their validity. The patient's opinions about the nature of lead poisoning and his apprehension concerning the effects

of the disease upon his future health and upon his present and future economic status must be appraised carefully particularly because problems of compensation often become a major consideration

The important objective manifestations of lead intoxication some combination of which may be seen in the usual case in clude severe cachexia and weakness enteric colic without significant fever leukocytosis or evidence of peritoneal inflammation weakness or paralysis with or without atrophy and without sensory changes of the extensor muscles of one or more of the extremities involving the lower extremities only rarely in the adult toxic encephalopathy to be differentiated from infectious or viral encephalitis or hypertensive encephalopathy

All but the most typical and uncomplicated cases of lead poisoning require diagnostic elucidation by means of either presumptive or specific and incontrovertible evidence that abnormal and dangerous quantities of lead have been absorbed by the patient Such evidences of themselves with the exceptions that will be indicated are not signs of intoxication but of absorption Of these only one can be observed in the course of the usual physical examination—the lead line of blue black deposit in gingival margins that are the site of an associated gingivitis This must be differentiated from deposits of other black metallic sulfides from the normal gingival and buccal pigmentation of dark skinned races and from the purplish blue margins of gingival congestion Since a "lead line" may occur when the lead content of the tissues is insufficient to cause illness it must be considered as evidence of abnormal but not necessarily toxic absorption of lead

Other presumptive but nonspecific laboratory evidence includes the following roentgenographic demonstration of the presence of opaque substances in the alimentary tract of the small child from his having swallowed bits of paint or fragments of painted objects the presence of the lines of metaphyseal density in the bones of young children microcytic hypochromic anemia and basophilic granulation of the erythrocytes and the finding of abnormal concentrations of coproporphyrin III in the urine The nonspecific anemia of lead intoxication is not always demonstrable and the stippling of the erythrocytes is in no wise differentiable from that found in a variety of other diseases The finding of coproporphyrin III in abnormal

quantities although in all probability one of the earliest signs of a toxic effect following the absorption of lead is lacking in specificity and is too variable to be more than a contributory bit of diagnostic information The results of these procedures are of value when combined with other satisfactory clinical appraisals of a patient and his exposure to lead and may establish a body of circumstantial evidence that is entirely convincing Nevertheless a conclusion arrived at by these nonspecific clinical and laboratory methods may not be valid especially in children

The procedure of choice in establishing the extent of the patient's absorption of inorganic lead is that of a precise determination of the lead content of his whole blood The same purpose can usually be accomplished by the determination of the general rate of excretion of lead in the urine In patients with intoxication due to tetraethyl lead only the analysis of the urine is helpful since tetraethyl lead and its major degradation products are not taken up by the erythrocytes Because of the variability of the urinary excretion of lead and the frequency of contamination of the urine during its collection the sampling and analysis of the urine are considerably more troublesome than the corresponding procedures carried out on blood In most instances the analysis of both blood and urine is more useful than that of either alone The results of determinations of lead in samples of blood or urine should be ignored utterly by the clinician unless he has sound reason for trusting their reliability The procedures of sampling and analysis require special knowledge and experience for their proper performance and grossly incorrect and utterly misleading results are obtained regularly unless special facilities are available

The threshold value in the blood which is indicative of a clinically significant degree of absorption of inorganic lead is fairly sharply defined at 80 micrograms per 100 gm of whole blood The corresponding value in the urine is somewhat less sharply defined at about 200 micrograms per liter It is unwise to depend upon the results obtained by the analysis of samples of urine of small volume or of one sample of large volume (1 to 2 liters or more) unless it is accompanied and confirmed by analysis of the blood The demonstration of the presence of high levels of lead concentration in the urine and blood of the patient or in the tissues at necropsy is not in itself evidence of lead

**intoxication** These findings must be accompanied by evidence of illness that is characteristic of or consistent with the disease

**Prevention** It is sufficient for the purposes of this presentation to point out that the medical and engineering techniques of industrial hygiene are adequate to prevent occupational lead poisoning when rigorously employed. Despite this fact many cases of industrial lead poisoning are seen by physicians in private practice and it is essential that the latter should take steps to prevent the recurrence of such illness among their patients. They should also be alert to preventive measures in the community and especially in the household since they more than any other persons have the opportunity to recognize the non occupational hazards in the environment of the families under their care. The physician should find out whether or not the industrial conditions which led to his patient's bout of intoxication have been corrected if they have not he should stimulate the necessary corrective action. He should not permit his patient to incur further exposure without at least assuring himself that the "body burden" of lead of his patient as revealed analytically has reached a reasonable approximation of a normal level. The causes of nonoccupational lead poisoning in the adult or infant should be established if possible and corrective measures should be advised.

**Treatment** The first step in the treatment of lead poisoning is to terminate exposure and absorption. Once exposure has been obviated absorption may be reduced and ended by the judicious use of saline cathartics in patients who are obstipated and who may have significant amounts of lead in their alimentary tracts.

The therapy of lead poisoning is designed to combat certain clinical manifestations of the disease which in themselves may result in death or serious sequelae to relieve distressing symptoms and to promote the elimination of lead from the body. There is no antidote as such for the effects induced by lead when it is present in the body in toxic concentrations. On the other hand the uncomplicated intoxication tends to be self limited and signs of illness subside following the cessation of excessive absorption when the lead content of the body is lowered by normal excretory processes and nutrition can be restored.

Lead encephalopathy in early childhood has a mortality of 25 to 30 per cent and produces irreversible brain damage in an

appreciable proportion of the survivors. The greatest threat to the life and mentality of the child appears to be increased intracranial pressure. This has been controlled when other measures have failed by craniectomy and the opening of the dura. If such intervention fulfills the hope it has inspired it should be undertaken early in the course of the serious case in order to prevent serious brain damage.

In tetraethyl lead poisoning with its potentially high mortality death appears to result from exhaustion since apparently successful therapy has combined prolonged and intensive sedation by the use of barbiturates with general nutritive and supportive therapy.

The avoidance of permanent paralysis and contracture as sequels of severe extensor weakness or paralysis of the extremities appears to depend in large part upon early recognition of the partial disability prompt and sufficiently prolonged discontinuance of occupational absorption of lead and appropriate physiotherapy including splinting when indicated. The administration of large doses of vitamin B<sub>12</sub> has been regarded by some as advantageous.

Colic the most distressing symptom in the usual adult patient is best relieved by the slow intravenous injection of 10 ml of a 20 per cent solution of calcium gluconate. A similar amount may be given intramuscularly to prolong the effect. Other drugs which relax smooth muscle may be used effectively for the relief of lead colic. There is a fairly general belief however that calcium salts give relief more completely and more promptly.

The anemia of lead poisoning can be treated in the same way as any other secondary anemia. Only in those situations in which nutrition has been and continues to be a serious problem does it seem to be relatively intractable.

*Expediting the elimination of lead from the body is of great importance.* The simplest and best way of accomplishing this objective short of the use of agents like dimercaprol (BAL) or edathamil disodium calcium (disodium calcium versenate) is to increase the output of water. The rate of urinary output of lead can be increased by almost one half by merely doubling the fluid intake this does not produce significant electrolyte loss. In itself the forcing of fluids is not recommended as an adequate method of therapy but it constitutes a valuable adjunct to treatment. No other known therapeutic procedure can achieve comparable increase in the elimination of

lead other than the two agents indicated above. Therapeutically induced shifts in the acid base equilibrium of the body as well as gross changes in the calcium metabolism fail to influence significantly the retention of lead within or its loss from the body.

The administration of BAL promotes a brief and highly dramatic change in the distribution of lead in the soft tissues of the body, including the blood which in essence is characterized by a prompt release of lead from the erythrocytes into both the soft tissues and the urine. Within minutes after the administration of this agent and for some hours the urinary excretion of lead is greatly augmented. After eight to twelve hours however the concentrations of lead in the blood and urine will have returned approximately to the levels found prior to treatment, the end result being that a few milligrams of lead, an insignificant fraction of that which has been added to the body stores, have been lost from the tissues, mostly from the blood. Some degree of risk is associated with this procedure, at least theoretically, in that the lead-dithiopropanol complex is not free of toxicity. Since this therapy neither relieves symptoms nor promotes lead excretion effectively, this form of therapy has nothing to recommend it.

The intravenous administration of edathamil disodium-calcium has not proved to be a dependable means of relieving the symptoms of lead poisoning of the usual type, e.g. colic, nor of saving seriously threatened lives. This form of therapy does promote effectively the loss of lead from the body and serves to reduce the duration of the period in which symptoms of intoxication may recur. There is also some suggestive evidence that it shortens the period of illness and disability. An acceptable therapeutic regimen is that of administering this drug in dosages up to 60 mg per kg of body weight per day by intravenous drip in saline or glucose solution. (There appears to be no contraindication to the administration of this same dose in 2 subcutaneous injections per day.) This is repeated daily for five days and after an interval of seven to ten days after the fifth day of treatment the level of lead concentration in the blood is determined. If as will often be the case the concentration of lead is within the dangerous range (0.08 mg or more per 100 gm) the five day course of treatment is repeated. These interrupted courses of therapy continue until the concentration of lead in the blood is

within the normal range (not in excess of 0.06 mg per 100 gm). By the time the lead in the blood has reached this level the symptoms of the adult patient will have subsided and he will be on the road to recovery. The problem of the child recovering from encephalopathy as well as that of the adult who anticipates his return to work are still ahead, however, in that both may have in their skeletons after the removal of most of the lead from their soft tissues quantities of lead which while equilibrium between the skeleton and the soft tissues is being restored, may raise the lead content of the latter to dangerous levels. At such a time the concentration of lead in the blood will not have returned to its initial high level but it may be considerably in excess of 0.08 mg per 100 gm. For this reason in the further management of the case the concentration of lead in the blood should be determined at intervals of a month or six weeks after the successful response to the first several courses of therapy and the therapy should be resumed as often as the blood level returns to the dangerous range.

A less precise therapeutic regimen is necessary when the timing of the steps in this procedure cannot be dictated by the results obtained from the analytical laboratory and a simpler regimen can be employed successfully in the ordinary case of industrial lead intoxication. Thus three or four courses of treatment separated by intervals of a week can be given to any patient and when it is known that the patient's exposure to lead was severe or prolonged further courses can be given. It is doubtful however that the best and most favorable therapy can be provided especially for a dangerously poisoned child without precise analytical information from time to time as to the extent to which the therapy has accomplished its purpose.

In view of the greatly diminished effectiveness of edathamil disodium calcium when administered by mouth and because of the lack of effective control of the therapy itself or of the beneficial or potentially harmful effects induced by its use, there seems to be no good reason for administering it orally.

## Methemoglobinemia and Sulfhemoglobinemia

### (Enterogenous Cyanosis)

**Definition** Methemoglobinemia exists when a greater than normal concentration of methemoglobin is present in the circulating red blood cells. Sulfhemoglobin is not normally present in the circulation. The two conditions are frequently coexistent and when clinically apparent are characterized by a cyanosis which differs from that produced by excessive amounts of reduced hemoglobin.

**Biochemistry** In hemoglobin the iron atom is in the ferrous state and is bound by coordinate bonds to the four nitrogen atoms of the pyrrole rings. There are two free coordinate bonds which permit reversible oxygenation to form oxyhemoglobin. Methemoglobin is formed when the iron is oxidized to the ferric state. In this form it cannot be oxygenated and is therefore useless for oxygen transport. The oxidation is quite reversible and methemoglobin is readily reduced to hemoglobin by appropriate reducing systems.

The precise chemical structure of sulfhemoglobin has not been determined. It may be produced by the action of hydrogen sulfide on oxyhemoglobin. Sulfhemoglobin cannot be oxygenated nor can it be reconverted to hemoglobin.

An aqueous solution of hemoglobin in contact with oxygen is almost wholly oxidized to methemoglobin. In oxygenated plasma however dissolved hemoglobin reaches an equilibrium in which only slightly more than half is in the form of methemoglobin while in the normal erythrocyte an equilibrium is maintained in which less than 1 per cent is in the form of methemoglobin.

The equilibrium in plasma depends on

the presence of normally occurring reducing substances that of the red cell requires the activity of a rather specific enzyme system. Lysis of the erythrocyte inactivates this system which uses glucose and lactate. There is evidence which suggests that its function depends on an adequate and continuing supply of reduced DPN.

Methemoglobinemia occurs whenever there is dysfunction of this enzyme system or when oxidants in the circulation oxidize hemoglobin at a rate which exceeds the reducing capacity of the system.

The determinants of sulfhemoglobin concentration are not well understood. In clinically encountered concentrations its presence does not significantly alter the life span of the red cell. Since it cannot be reconverted to hemoglobin it leaves the circulation only when the red cell containing it is destroyed. When the factors which caused sulfhemoglobin formation are removed its concentration diminishes by slightly less than 1 per cent of its initial value per day.

**Pathological Physiology** Acute or secondary methemoglobinemia has two detrimental effects on the organism. First that portion of hemoglobin which is oxidized to methemoglobin is no longer available for oxygen transport and the condition is analogous to an anemia of comparable degree. Second Darling and Roughton demonstrated that the presence of methemoglobin in the circulation altered the dissociation curve of the remaining oxyhemoglobin in such a way that tissue oxygen tensions must fall to lower than normal values before the remaining oxyhemoglobin yields its oxygen. This is analogous to but less marked than the shift in oxyhemoglobin dissociation curve caused by carboxyhemoglobin.

Methemoglobinemia of less than 40 per cent produces little respiratory or cardiovascular change at rest but concentrations of 10 to 20 per cent are accompanied by significant elevations of blood lactate in men who are performing moderately heavy work.

Similar handicaps are thought to be imposed by sulfhemoglobinemia but these have not been studied in detail.

**Etiology** Primary or congenital methemoglobinemia (qv) is an inborn error of metabolism caused by failure of function of the intracellular reducing enzyme system.

Secondary or acute methemoglobinemia is produced by a group of compounds the nature and mode of action of which have

been extensively reviewed by Bodansky. These compounds include direct oxidants which can be observed to have a powerful *in vitro* action and a large group of aromatic nitro and amino compounds with little or no direct oxidant action *in vitro* but very powerful methemoglobin formation *in vivo*. In spite of intensive study the nature of the intermediate compound by which this group produces methemoglobinemia has not yet been firmly established.

The direct oxidants include nitrites, chlorates and quinones. Nitrates particularly in infants may be reduced to nitrites by bowel action. Severe methemoglobinemia in infants has followed the ingestion of nitrate contaminated well water and the use of bismuth subnitrate for diarrhea.

Three important groups among the indirect oxidants merit discussion.

1. *Aniline and Its Derivatives*. Diapers freshly stamped with aniline marking ink have caused dangerous and even fatal methemoglobinemia in infants. Similar poisonings have been caused by percutaneous absorption from freshly dyed shoes and blankets. Aniline derivatives are also responsible for the methemoglobinemia which may be caused by the ingestion of colored wax crayons.

■ *Earlier Sulfonamide Derivatives*. High blood concentrations of sulfanilamide, Prontosil, sulfathiazole and sulfapyridine are almost uniformly accompanied by some degree of methemoglobinemia. This has been very rare and mild with sulfadiazine and sulfamerazine.

3. *Acetanilid and Phenacetin (Acetophenetidin)*. Analgesics containing these two compounds may be obtained without prescription and are consumed in enormous quantities; they are among the most common causes of methemoglobinemia and sulfhemoglobinemia.

Sulfhemoglobinemia may be produced *in vivo* by most of the compounds which cause methemoglobinemia and the two conditions frequently coexist.

*Enterogenous Cyanosis*. Under this heading a small and clinically rather ill defined group of cases caused great interest in the first quarter of this century. They were characterized by sulfhemoglobinemia and/or methemoglobinemia. Bowel dysfunction was found in the great majority and headache was a frequent symptom. The disorder was thought to be caused by the absorption of an enterogenous oxidant. Shortly after 1925 when it was demonstrated that

phenacetin could produce sulfhemoglobinemia as well as methemoglobinemia, this entity practically disappeared from the literature.

*Symptoms and Signs*. In mild cases cyanosis is often the main symptom as well as the cardinal sign. In more severe instances this is accompanied by the syndrome of acute hypoxemia with exertional dyspnea, headache, dizziness and blurring of mental functions. In extreme instances this syndrome may progress to stupor or even coma.

*Diagnosis*. Whenever cyanosis exists without concomitant evidence of cardiovascular or respiratory dysfunction, the presence of methemoglobinemia and/or sulfhemoglobinemia should be suspected. If venous blood retains its brownish hue when it is shaken vigorously with air for fifteen minutes suspicion is confirmed. Under these conditions reduced hemoglobin is almost completely oxygenated to scarlet oxyhemoglobin. Examination of a 1:100 aqueous dilution of blood with a hand spectroscope finally establishes the diagnosis. Methemoglobin shows a well defined absorption band at 630  $m\mu$  which disappears almost immediately after the addition of a few drops of 5 per cent KCN solution. Sulfhemoglobin's absorption band at 618  $m\mu$  is unaffected by the addition of KCN. Quantitative studies require more complex spectrophotometric and gasometric techniques.

*Treatment*. Mild cases require no treatment other than the withdrawal of the causative chemical. Concentrations of sulfhemoglobinemia sufficient to endanger life do not seem to occur clinically and there are no known measures which will convert sulfhemoglobin to hemoglobin. The reducing enzyme system of the erythrocytes will rapidly reconvert methemoglobin to hemoglobin when the disturbing oxidant disappears from the circulation.

If the degree of methemoglobinemia is of sufficient degree to cause significant hypoxia, an intravenous solution of 1 per cent aqueous methylene blue in dosage of 1.0 to 2.0 mg. per kg. of body weight should be administered. If injected over a period of several minutes this dosage causes no undesirable side effects in man and very rapidly reconverts methemoglobin to hemoglobin. If methemoglobinemia recurs as a result of the persistent action of some agent such as nitrobenzene, the administration of methylene blue may be repeated at hourly intervals.

## Chronic Bromide Poisoning

## (Bromism)

**Definition** Chronic bromide poisoning occurs when the bromide ion is ingested in amounts or under circumstances which cause its concentration in body fluids to rise to levels at which its depressant action produces toxic effects on the central nervous system. This level varies widely in different individuals but may be as low as 50 mg per 100 ml.

**Etiology** The bromide ion is as readily absorbed as the chloride ion and is distributed through the same fluid compartments. Under normal conditions renal homeostatic mechanisms maintain the total plasma halide concentration relatively constant at approximately 100 mEq per liter. The renal tubule normally reabsorbs a slightly higher percentage of filtered bromide than chloride ion. Whenever the bromide ion constitutes a significant proportion of ingested halide, the bromide concentration in body fluids rises until an equilibrium is reached at which renal excretion equals ingestion.

**Incidence** Wuth's classic article in 1927 recorded that 21 per cent of the patients admitted to the psychiatric division of the Johns Hopkins Hospital over a period of six months had bromides in their blood and signs of intoxication. In 77 per cent of a series of patients admitted to a state psychopathic hospital excessive blood bromide concentrations were found. Unsuspected bromide intoxication was the sole reason for the admission of almost 2 per cent. In spite of continued published warnings the incidence of bromism is still alarmingly high.

Among the several reasons for this sad

state of affairs are (1) The symptoms of the underlying disturbance for which bromides are taken and those of bromism itself are often very similar since bromide may temporarily alleviate the very symptoms it produces. Increasingly large amounts may be administered to a person already suffering from bromism. (2) Many proprietary "nerve tonics" and analgesics contain significant quantities of bromides and may be obtained in unlimited quantities without prescription. (3) Even physicians may overlook the fact that the toxicity as well as the efficacy of a given dosage of bromide ion can be estimated only when the patient's total halide intake is known—a dosage which may be totally ineffective in a person with a high salt intake may rapidly produce severe poisoning in a patient on a cardiac regimen with markedly limited chloride ingestion. Finally complications such as arteriosclerosis, alcoholism and systemic disease may increase a patient's susceptibility to bromide intoxication.

**Symptoms** The symptoms of bromism vary greatly from patient to patient not only in their pattern but in their relationship to the blood bromide level. Among the chief symptoms in order of frequency are headache, irritability, emotional instability, weakness, lethargy, slurred and irrelevant speech, disorientation, hallucinations and loss of memory. The Council on Pharmacy and Chemistry of the A.M.A. noted that any organic reaction type may be simulated.

Bromide rash is found in less than 25 per cent of cases of bromism.

**Diagnosis** Although a high index of suspicion is a prerequisite, the symptoms and signs of bromism are so protean and so subtle and often so similar to those of the disorder for which bromide is administered that it is only through the determination of the concentration of bromide ion in the blood that suspicion can be substantiated. Wuth's gold chloride method is readily performed and is accurate enough for clinical purposes. The correlation between symptomatology and blood bromide concentrations is only rough but concentrations of 75 mg per 100 ml and more are suggestive and concentrations more than twice this are definitely toxic.

**Treatment** Bromide ingestion is stopped and renal elimination of bromide ion from the body is speeded by means of a high fluid and chloride intake supplemented by mercurial diuretics which significantly increase bromide clearance. If the patient's

cardiac status permits fluid intake is increased to about 4 liters a day Chloride intake is augmented by the administration of 1 gm each of enteric coated ammonium and sodium chloride

Dialysis by means of the artificial kidney will very rapidly remove bromide ion from the body but such heroic therapy is infrequently indicated

The rate of bromide ion excretion by the kidney falls as the blood bromide concentration diminishes so that many months may be required completely to rid the body of bromide Symptoms and signs of bromide intoxication may outlast by days or weeks the return of blood bromide concentrations to accepted therapeutic values

The restlessness exhibited by most patients with severe poisoning has been difficult to control with conventional sedatives chlorpromazine has been reported to be of value under these circumstances

## Salicylate Poisoning

**Definition** The administration of sufficiently large dosages of salicylates produces a group of symptoms known as salicylism characterized by headache dizziness tinnitus diminution in hearing mental confusion sweating nausea vomiting and upper abdominal discomfort occasionally with gastrointestinal hemorrhage

Higher plasma salicylate levels cause stimulation often followed by depression of the central nervous system. Consequently significant changes in the acid base and electrolyte structure of the body fluids are produced. These disturbances are known as "salicylate poisoning."

**Incidence** More than 9 000 000 pounds of aspirin (acetylsalicylic acid) alone are consumed annually in the United States

Although the relative incidence of poisoning among the millions of users is low the absolute figure represents a substantial and needless loss of life. In 1952 there were 113 reported deaths from salicylate poisoning. 86 of these occurred in children under five years of age.

**Morbid Anatomy** Petechial hemorrhages in the central nervous system and in various viscera are a prominent feature. Recent studies of the brains of patients who died of salicylate poisoning demonstrate direct nerve cell damage and the lesions of a toxic encephalopathy.

**Pathological Physiology and Chemistry** Salicylates specifically increase the sensitivity of the respiratory center to the CO<sub>2</sub> hydrogen ion stimulus. Blood salicylate concentrations ranging from 12 to 16 mg per 100 ml increase the sensitivity of the center from 84 to 307 per cent. This is accompanied by a striking increase in minute respiratory volume. Individual sensitivity to a given concentration of salicylates varies widely although 35 mg per 100 ml has been cited as the toxic level in children. Unequivocal instances of toxicity have been observed in acutely ill children with blood levels as low as 9 mg and less per 100 ml.

The increased respiratory minute volume leads to a fall in arterial CO<sub>2</sub> tension and CO<sub>2</sub> content and a rise in pH. The rise may be sufficient to produce frank tetany. Renal excretion of fixed cations lessens the pH increase. In the milder instances of salicylate poisoning usually seen in older children and adults this picture of respiratory alkalosis with slight reduction in buffer base predominates. In more severe cases in adults and older children and in most cases of children under six years old this phase is followed by a significant fall in buffer base and the appearance of a true metabolic acidosis.

The acidosis cannot be accounted for by the actual quantity of salicylate present and the relatively small renal excretion of fixed cation in respiratory alkalosis. It is hypothesized that the salicylate in these cases interferes with oxidative enzyme systems.

Large doses of salicylates also cause prothrombinopenia.

**Symptoms and Signs** In adults the symptoms of salicylism usually precede salicylate poisoning. In children these are rarely noted and hyperpnea and vomiting are the striking manifestations. Fever is a prominent feature of the most severe degree of poisoning and sweating often adds to the

dehydration. In instances of therapeutic overdosage they are superimposed on the syndrome of the underlying disease.

Convulsions, delirium and coma are observed not infrequently in grave poisonings.

**Diagnosis.** Unexplained hyperpnea and vomiting in a child should raise the possibility of salicylate poisoning. Since hyperglycemia may occur in salicylate poisoning the differentiation from diabetic acidosis must be kept in mind. The presence of salicylates in urine may be established by adding ferric chloride and observing a purple ring which does not disappear with boiling. Determination of the blood salicylate concentration will confirm the diagnosis.

**Prognosis.** Prognosis must be guarded. Fatalities have occurred after electrolyte disturbances have been restored to normal.

**Treatment.** In instances of accidental poisoning gastric lavage with tap water should be performed at once. Methyl salicylate in particular may remain in the stomach for many hours.

Unless facilities are available for the accurate determination of arterial or capillary blood pH and CO<sub>2</sub> content, intravenous therapy should be restricted to the administration of physiological saline solution to combat dehydration and of glucose for ketosis. If these parameters can be precisely measured, cautious correction of the pH and electrolyte disturbances should be attempted. In contrast to the situation in methanol poisoning, one should err on the side of under rather than overtreatment.

Prophylactic administration of 50 to 75 mg of menadione sodium bisulfite and of up to 0.5 gm of ascorbic acid in adults is worthwhile. Vitamin K<sub>1</sub> oxide should be given for active bleeding.

Controlled intermittent positive pressure respiration after curarization using equal mixtures of nitrous oxide and oxygen in a closed system has been favorably reported. If the necessary trained team is available and the gravity of the poisoning warrants it, salicylate concentrations can be rapidly reduced and normal electrolyte structure restored by dialysis with the artificial kidney.

Since the central nervous stimulation caused by salicylates is frequently followed by depression, sedation of any sort must be administered with great caution. Calcium salts and CO<sub>2</sub> inhalation have little if any value.

## Methyl Alcohol Poisoning

Methyl alcohol (wood alcohol, methanol) is widely used as an industrial solvent but its current medical importance stems from its employment as an adulterant or substitute for ethyl alcohol in beverages.

**Incidence.** Outbreaks of methanol poisoning usually occur when access to beverages containing ethyl alcohol is restricted by regulation or when economic conditions and a high tax on beverage alcohol encourage its use as an adulterant. Lack of appreciation of its terrible toxic properties is in part the responsibility of the medical profession, which was long confused by its apparent lack of toxicity in several species of commonly used experimental animals. A single batch of illicit whiskey produced 323 cases of poisoning and killed forty-one people.

**Morbid Anatomy.** Meningeal petechial hemorrhages and submucosal subepicardial and subpleural hemorrhages are usually seen. Cerebral edema and necrosis of the retinal neurons are consistent autopsy findings, but the optic nerves and tracts are usually spared. Severe pancreatic necrosis secondary to acute hemorrhagic pancreatitis is frequent in fatal cases.

**Pathological Physiology and Chemistry.** Methanol like ethanol produces an irregularly descending depression of the central nervous system. In equal doses this in toxicant action of methanol is much less than that of ethanol. The noxious action of methyl alcohol results from the severe acidosis produced by it in primates and a highly specific reaction of its metabolites on the neurons of the retina. As little as 0.1 ml has caused death and blindness has been reported after the ingestion of only 4 ml. On the other hand, survival after drinking as much as 540 ml has been observed.

Gastrointestinal absorption of methanol is prompt but a latent period between in-

gestion and the appearance of toxic symptoms is usually observed this latent period is usually about twenty-four hours although it may range from less than one to more than forty hours.

Methanol is oxidized in the body to formic acid. Formaldehyde is a probable step in this oxidation. The severe acidosis observed in many patients (four patients in the Atlanta outbreak showed a carbon dioxide combining power of zero as determined by the Van Slyke method) can not be accounted for by the quantity of formate formed. It is postulated that methanol and/or its metabolites inhibit some oxidative enzyme systems and permit the accumulation of lactic and unidentified organic acids.

In excised liver slices and in experimental animals methanol is oxidized only one-seventh as rapidly as ethanol. It may persist in the body for as long as a week after ingestion. The presence of ethyl alcohol significantly retards the oxidation of methanol.

**Symptoms and Signs.** The symptoms of methyl alcohol poisoning are usually complicated by those of varying degrees of ethanol intoxication since both alcohols are usually ingested simultaneously. Visual disturbances and abdominal pain are among the most characteristic and headache is common. Dyspnea is an infrequent complaint.

Dilated nonreactive pupils, hyperemia of the optic disks with varying degrees of retinal edema and rigidity of the abdominal muscles are striking physical signs. The skin is often cool and clammy. Kussmaul breathing is not prominent.

**Diagnosis.** Methyl alcohol poisoning should be considered in any patient complaining of abdominal pain and visual disturbance. Suspicion should be heightened by a history of a recent drinking bout and hyperemia of the optic disks and acidosis in association with these makes the performance of a specific test for methanol in the blood worthwhile.

**Prognosis.** Since death from respiratory failure may occur in spite of correction of the acidosis, prognosis must be guarded. The likelihood of permanent visual impairment is almost impossible to assess at the outset.

**Treatment.** Whenever a case of methanol poisoning is diagnosed, efforts should be made to bring under medical observation all persons who ingested the same beverages as did the patient.

The cornerstone of treatment is the cor-

rection of the acidosis. Enormous amounts of alkali may be required as much as 420 gm of sodium bicarbonate have been administered in twenty-eight hours with benefit. Serum carbon dioxide content or capacity should be determined at the start of treatment and the course of therapy followed with serial determinations. Since vomiting is often a problem, alkalization is usually best accomplished by the intravenous administration of a 3 to 5 per cent solution of sodium bicarbonate in 5 per cent dextrose and water. The slow oxidation of methanol may lead to recurrence of acidosis after initial correction and may require further therapy. After therapy is under way, hypokalemia should be watched for and treated if necessary.

Current evidence suggests that the toxic effects of methanol may be lessened and even prevented by the concurrent administration of ethyl alcohol. A maintenance level of 0.1 per cent ethanol is suggested. In a person whose blood contains none, this level may be promptly achieved by administering 60 ml of ethanol and it may be kept at this level by giving 1 ml per hour.

The eyes should be protected from light. Supportive measures such as oxygen for hypoxia and short-acting intravenous barbiturates for convulsions are used as indicated.

#### Radiation Injury

**Definition.** The term "radiation injury" describes a number of clinical syndromes which have exposure to ionizing radiation as a common etiology. The term "radiation sickness" has generally been used to designate the nausea and loss of appetite which follow exposure to penetrating radiations.

used for therapeutic purposes. Radiation injury in a less restrictive sense is reserved to indicate those clinical and subclinical manifestations which result from toxic local or general exposure to penetrating radiations originating from an external source or from the presence of radioelements within the body itself. For practical purposes the agents capable of producing injury to the body are x rays, gamma rays, fast and slow neutrons, beta and alpha particles. Radiation which arises from sources outside the body is conventionally referred to as external radiation, while radiation arising from radioelements within the body is referred to as internal radiation.

**Etiology.** Beta particles are energetic electrons which travel several millimeters in tissues; ordinary alpha particles are helium nuclei which travel a maximum of about 40 microns in tissue, whereas energetic x rays, gamma rays or fast neutrons are many times more penetrating than either  $\lambda$  rays and gamma rays expend their energy and produce biological effects in cells and tissues by the acceleration of electrons (hydrogen nuclei) and slow neutrons by the release of gamma rays or fast atomic nuclei when they are captured by the atomic nuclei of the chemical elements present in the tissue. Thus the significant sources of external radiation include all those mentioned except alpha particles. Internal radiation involves alpha and beta particles and gamma rays.

The clinical manifestations of exposure to radiation vary because the injury sustained depends on the type and energy of the radiation, the area of the body exposed and the dose and the length of time over which a given dose is sustained. The biological effects of penetrating ionizing radiation delivered to the whole body within a few milliseconds or minutes will differ remarkably from the effects resulting if this same amount of radiation is sustained over a period of weeks, months or years. The degree of selective localization of radioelements within the body and the half life of the isotope are additional factors to be taken into consideration.

Radiation exposure until 1934 was largely confined to professional and technical personnel involved in the preparation of radium and its by products to persons employed in the manufacture of x ray tubes and equipment or engaged in the diagnostic and therapeutic use of x rays

and gamma rays and to a lesser extent to persons using these radiations as tools of physical research. The invention of the cyclotron by Lawrence in 1934 brought the added hazard of the fast neutron and gamma rays and artificial radioelements. In 1942 the first chain reacting uranium pile was placed in operation by Enrico Fermi adding as a consequence a radiation hazard several thousand times greater than that which had existed theretofore. Thus the uranium pile, the processing of the many radioelements produced in the fission reaction and the increased medical and research uses of radiation and radioelements and the eventuality of atomic warfare make the prevention, diagnosis and treatment of acute and incipient radiation injury a public health problem of growing national importance.

The entry of radioactive elements into the body may occur as a result of ingestion (deliberate or accidental), inhalation, introduction through penetrating wounds, absorption through the skin or deliberate intravenous administration as in the use of these materials for therapeutic purposes.

**Units of Measurement and Permissible Exposure.** In 1931 a committee established by the National Bureau of Standards set 0.1 roentgen (r) per day of x rays or gamma rays as the permissible dose to which the human body could be exposed indefinitely without the production of harmful effects. The r is the unit of exposure dose and is that amount of radiation which will result in the absorption of 83 ergs per gm when wet tissue is exposed to it.

Later in 1951 the maximal permissible level of exposure was lowered to 0.3 r/m per week by the National Committee on Radiation Protection. The rem unit is that amount of radiation of any type which has the same biological effectiveness as 1 rad of 200 kv x rays. The rad is a unit of measurement that is rapidly becoming accepted as the most accurate and universal expression of dose. It is a unit which expresses the absorbed dose and is 100 ergs per gm of the absorbing medium.

It should be emphasized that the maximum permissible level of radiation for human beings is subject to many qualifying considerations, e.g., age, condition of health, general or selected population, and so forth. A comprehensive discussion of the subject may be found in Handbook 59, Permissible Dose from External Sources of Ionizing Radiation, National Bureau of Standards, 1954.

**Experimental Radiation Injury** Experiments on animals have been performed to give baseline information and to supplement the very limited data that are available on the effects of ionizing radiations in human beings. The reader is referred to papers by Prosser, Lorenz, Friedman, Dunlap, and Jacobson, since only a brief summary of these studies is presented here.

**Single Exposure (Whole Body) to Dosages in the Midlethal Range** The dosages of  $\gamma$  radiation required to kill half of irradiated groups of animals (within thirty days) of the species commonly used in laboratories are

Guinea pig	250 roentgens
Dog	325 roentgens
Goat	350 roentgens
Mouse	550 roentgens
Rat	650 roentgens
Rabbit	800 roentgens

In all these species death usually occurs between the sixth and the fourteenth days. The chief pathological findings are confined largely to the hematopoietic system, the gastrointestinal tract, and the gonads. Doses below the midlethal point produce progressively less damage in these species. Single doses below 25 roentgens produce neither hematological nor histopathological evidence of effect.

**Repeated Exposure (Whole Body) to Relatively Low Dosages in the Permissible Range** Experiments on mice, guinea pigs, and rabbits indicate that a dosage of 0.1 roentgen per day (radium gamma rays) is tolerated throughout the normal life span of the animal (more than three years) without the appearance of recognizable evidence of damage except for an increased incidence of ovarian tumors in female mice. With dosages of 1, 2, 4, or 8 roentgens per day, the hematopoietic depression, shortening of the life span, and the incidence of sterility and of benign and malignant tumors becomes increasingly more significant.

**Morbid Anatomy** The pathological changes associated with whole body exposure to lethal or semilethal doses of penetrating radiations (400 to 600 roentgens) as described by Warren are essentially limited to the findings of an aplastic marrow, depletion of lymphatic tissue, destruction and atrophy of gonadal tissue, edema, mucosal sloughing, and hemorrhage in the gastrointestinal tract, multiple pyogenic abscesses or other infection, hemorrhages in the skin, subcutaneous tissue, muscle, and viscera, and an increase in tissue mast cells. Erythema, edema, loss of skin surface

with delayed healing, and epilation are common after exposure to doses of about 600 roentgens or more. Doses below the lethal range produce correspondingly less pathological change.

Acute or chronic exposure to whole or partial body radiation below the lethal but above the permissible range may produce no demonstrable pathological effects or the effects may be confined to degenerative changes in the hematopoietic system, gonads, skin, and eyes, and to the induction of neoplasms.

The pathological changes associated with radioactive elements such as radium, strontium, and plutonium, which are deposited largely in bone, are a hyperplastic immature or aplastic type of marrow rarefaction of bone, fracture, and incomplete healing, irregularities of the epiphysis, and growth arrest. As described by Martland, sarcomas of bone are complications of these long-lived bone seekers.

**Pathological Physiology and Chemistry** Absorption of radiation in cells and fluids of the body is attended by release of energy. This release of energy is considered by many authorities to consist of transient ionization of water molecules, followed by the formation of hydrogen peroxide and chemical radicals which in turn inhibit or denature the sensitive enzymes or enzyme systems. There is a great difference in the radiosensitivity of cell types within the body. The radiosensitivity of the same cell type differs from person to person and from species to species. Rapidly proliferating cells such as lymphocytes and spermatogonia are more radiosensitive than the cells of the brain or the kidney. Cells in mitosis, especially in prophase, are more susceptible to radiation injury than cells in the resting phase. It is also apparent that a latent period, varying from minutes to years, may be interposed between the initial effect of irradiation on cells and their death or functional derangement.

In acute lethal or midlethal radiation injury, regeneration and repair proceed too slowly to overcome the overwhelming pathological alteration induced by the widespread death of cells. In chronic radiation exposure, regeneration and repair may so closely parallel injury that pathological alteration does not become manifest for long periods of time, if at all.

No single organ system or tissue appears to be universally critical in producing death after lethal or midlethal whole body exposure to single doses of external radiation. Death appears to occur usually as a result

of a combination of pathological processes which include plasma and electrolyte loss, destruction of hematopoietic tissue, infection, hemorrhage and nonspecific toxemia.

The functional effects of acute or chronic external exposure, such as temporary or permanent sterility and amenorrhea, can usually be correlated directly with pathological changes in the ovary or testes. On the other hand, the altered capillary physiology, the role of histamine release, the loss of adrenal lipid, the increased incidence of neoplasia and accelerated aging process are as yet poorly understood from the standpoint of the mechanism of the acute or chronic radiation injury syndrome.

**Symptoms and Signs.** Injury from overwhelming doses to the whole body is followed within minutes to hours by severe nausea, vomiting and diarrhea, erythema and edema of the skin, severe prostration, circulatory collapse, coma and death within forty-eight hours.

Lethal or near lethal doses (400 to 600 roentgens) produce severe weakness, malaise and prostration, nausea and vomiting and diarrhea within a few hours after exposure. Fever appears within the first twenty-four hours. Infections such as painful ulcerations in the throat or about the teeth, skin abscesses or evidence of other local or more general infection appear after two to four days. Bleeding from the gums and bloody diarrhea usually appear at the end of the first week after exposure and may increase in extent and severity through the third week or more unless recovery or death occurs. Disorientation may appear early and progress to coma. If patients survive infection, hemorrhage and shock resulting from plasma and electrolyte imbalance in the first three to four weeks, anemia may be sufficiently severe as a result of hemorrhage and failure of marrow recovery to produce death. Temporary or permanent sterility, amenorrhea and an increased incidence of acute and chronic leukemia are observed in survivors.

Whole body exposure to single doses of 200 to 400 roentgens of penetrating radiation can be expected to produce marked weakness, malaise, nausea, vomiting and diarrhea. Individual susceptibility will dictate the outcome of persons in the group in the absence of supportive treatment. All will have leukopenia and thrombocytopenia, but the seriousness of infection, anemia, hemorrhage and electrolyte imbalance will vary from mild to severe. Death can be expected to occur in less than

50 per cent of this group from circulatory collapse, infection, hemorrhage or combinations thereof. Temporary sterility and epilation will occur in an unpredictable number of the persons thus exposed.

Single doses of 100 to 200 roentgens can be expected to produce nausea, vomiting, anorexia, malaise, fever and diarrhea. These symptoms would appear early but would be transient. Leukopenia and thrombocytopenia would occur but variability in the severity should be expected. Hemorrhagic manifestations would be moderate or absent; an anemia would be unlikely. Recovery could be expected in all persons so exposed.

Single doses of 50 to 100 roentgens produce no symptoms or only a mild nausea and malaise. Reduction in leukocyte and platelet values of the peripheral blood may occur in an occasional person but will be transient. No symptoms or signs occur from whole body exposure to 25 roentgens or less.

Injury from chronic exposure to radiation of external origin produces local or general symptoms and signs depending on whether whole or partial body exposure was sustained. Delayed healing of abrasions or the development of painful benign or malignant ulceration in the friable, atrophic skin of the hands may be distressing. Weakness and fatigue are associated with the onset of a leukemia or the presence of an anemia and may also occur in circumstances in which only a leukopenia is demonstrable. Premature menopause with its attending symptoms in the female and sterility in the male with aspermia or morphologically abnormal sperm may occur. The development of lens opacities is attended with a gradual loss of vision.

The clinical picture produced by lethal amounts of radioactive elements such as radiophosphorus ( $P^{32}$ ) or radiostrontium ( $Sr^{90}$ ) is similar in most respects to that observed after lethal doses of whole body radiation from an external source except that the onset of symptoms is delayed. The symptoms preceding death are chiefly due to severe anemia, leukopenia and thrombocytopenia with widespread hemorrhage or infection or both, since these radioactive elements seriously affect the hematopoietic system. Lesser amounts of these and other radioisotopes produce signs and symptoms dependent on the degree of localization. For example, after the administration of radioiodine ( $I^{131}$ ) in single or divided doses sufficient to produce a remission in hyper

thyroidism hypothyroidism may insidiously supervene as a result of thyroid destruction

Since in therapeutic radiology every effort is made to minimize discomfort to the patient or damage to normal tissue complications are relatively rare Nausea and anorexia and malaise are frequently associated with therapeutic radiation involving abdominal viscera diarrhea may supervene in some instances Leukopenia thrombocytopenia and anemia occasionally complicate therapeutic irradiation when the portals involve hematopoietic tissue

**Diagnosis** The diagnosis of radiation injury after whole body exposure to a single burst of penetrating radiation in or near the lethal range as a result of accidents involving cyclotrons betatrons large gamma ray sources and nuclear reactors will offer no problem the difficulty will be found in establishing the exact or approximate dose received and thus the probable prognosis or in the case of an atomic bomb attempting to distinguish radiation injury from thermal and blast injury With doses below the lethal range but above 100 roentgens the characteristic symptoms of nausea vomiting diarrhea anorexia and malaise are likely to appear within hours of the exposure the leukopenia and thrombocytopenia follow within a week and anemia even later Temporary complete or partial epilation temporary sterility in both males and females and temporary amenorrhea in women should always be looked for after exposures in this range The diagnosis of radiation injury after accidental or therapeutic exposure of a part of the body to single or divided doses of penetrating external radiation may rest on the history since the local findings the symptoms and hematological picture will depend to a large extent on the size of the area irradiated and the total dose sustained

The diagnosis of radiation injury from chronic exposure to external radiation above the permissible range is based on the history of exposure plus such findings as dermatitis atrophy or distortion of the epidermal ridges of the fingers hyperkeratosis epilation indolent skin ulcers neoplasia sterility amenorrhea lens opacities and hematological abnormalities

Even in the presence of suggestive clinical or laboratory evidence of radiation injury from internal emitters such as radium and plutonium the diagnosis must be confirmed on the basis of the demonstration of evidence of actual deposition within the body This may be done by survey of the

body with a modified Geiger counter or isolation and identification of the radioactive element in the urine

**Treatment** In general there is no specific treatment for radiation injury Treatment of radiation injury from single doses in the lethal range consists largely in symptomatic supportive and prophylactic measures Maintenance of fluid and electrolyte balance with physiological saline and other necessary aids combating protein deficiency and vascular collapse by the liberal administration of plasma and whole blood parenteral feeding with glucose and protein digests prevention or management of infection with antibiotics management of blood loss with whole blood transfusion compression bandages for severe surface burns and liberal use of sedation such as morphine for pain and restlessness are the major steps to be taken In the event of an atomic bomb the treatment would be essentially similar except that the flash burns and penetrating wounds would require immediate attention The severe nausea vomiting and diarrhea which attend serious radiation injury respond poorly to any attempt at specific management Persons exposed to doses of whole body radiation below the midlethal range but from which gastrointestinal symptoms infection and hemorrhage of unpredictable seriousness may arise should be managed in accordance with the clinical and laboratory evidence of involvement

The treatment of accidental or deliberate exposure of limited areas of the body to external radiation with injury to vital internal organs or tissues or damage to the skin (erythema) will depend on the area involved and the severity of the pathological process

Treatment of evidence of radiation injury resulting from chronic exposure to penetrating external radiation should begin by removing the person from further exposure or reducing the exposure to permissible or negligible levels Such manifestations as radiation dermatitis atrophy of the skin indolent ulcers carcinoma of the skin leukopenia leukemia and lens opacities will require specific symptomatic supportive treatment or corrective surgery

The treatment of radiation injury following the entrance of massive doses of radioactive elements into the body is essentially similar to the treatment of massive exposure to penetrating external radiation No effective methods are available which materially hasten the excretion of radioactive elements fixed in the body The treatment of

the anemia, leukopenia, thrombocytopenia and hemorrhagic manifestations which follow therapeutic administration of radio phosphorus ( $P^{32}$ ), radiosodium ( $Na^{22}$ ) and radiostrontium ( $Sr^{90}$ ) is largely confined to blood transfusion and the use of antibiotics as indicated if local or general infection occurs.

**Prophylaxis** Prevention of radiation injury involves the maintenance of conditions which reduce the hazard of exposure to external and internal radiation to the permissible dose level or below. The techniques involved in working with radiations require special experience and knowledge. If chronic overexposure and disastrous accidents are to be avoided, orientation of personnel should precede work with penetrating radiations or radioactive elements. Such orientation should embrace (1) understanding of "permissible exposure" and basic knowledge of the biological effects and physical properties of radiation, (2) understanding of the principles of radiation protection from the various radiations, (3) ability to utilize existing instruments for determining a given radiation hazard, (4) familiarity with the techniques and procedures basic to work with these physical agents.

The supervisor must assume the responsibility for his professional and technical staff and demand and enforce observation of accepted standards of operation. One careless person working with radioactive elements can hopelessly contaminate a laboratory and jeopardize the health of his colleagues.

Even when the most stringent precautions are enforced to minimize radiation exposure, such as education of personnel, shielding of radiation sources and effective ventilation, the following additional precautions must be observed: (1) periodic medical examination which should include a general physical examination with special reference to evidence of atrophic changes in the skin or of dermatitis, (2) periodic hematological studies to detect leukopenia, thrombocytopenia or anemia, (3) daily monitoring of skin and clothing of personnel for contamination with radioactive elements, (4) periodic examination of urine, sputum, feces and exhaled air from personnel to detect actual presence of radio-elements in the body, (5) continuous monitoring of personnel during working hours in order to measure dose received (film badge, pocket electroscope, and so on), (6) periodic monitoring of laboratory facilities or radiation source in

stallation for evidence of radioactive contamination or unsuspected faulty shielding. This involves analysis of air samples in certain circumstances.

Evidence of actual overexposure of a person (physical measurements) or clinical or laboratory evidence of radiation injury should be followed by immediate removal of the person from all sources of further exposure until the situation can be properly assessed and remedial measures instituted if necessary. The decision whether a person once or repeatedly overexposed to radiation with or without evidence of radiation injury may or may not be allowed to continue work with radiation will be difficult to make with certainty.

#### Hypervitaminosis

**History** Since vitamins were first used as therapeutic agents, there have been sporadic reports of ill effects following their administration. Despite the size of the therapeutic dose, however, the administration of most of the vitamins is not followed by any untoward effects. The water-soluble vitamins tend to reach a certain concentration in the blood and are then quickly excreted. Undoubtedly cases of individual idiosyncrasy may produce unpleasant reactions to these substances even when taken in small amounts. Such symptoms are not those of hypervitaminosis. There is considerable evidence that repeated massive doses of the fat-soluble vitamins A and D sometimes produce so-called hypervitaminosis. This discussion will be limited to the hypervitaminosis caused by vitamin A and by vitamin D.

**Hypervitaminosis A** This term is used for a varied and sometimes bizarre condition arising from the administration of

massive doses of vitamin A. Numerous investigators have reported injurious effects following the administration of large doses of vitamin A to rats. The coats of the animals become rough and they develop cachexia, conjunctivitis and diarrhea, striations in the muscle fibers of the heart, degeneration of the testes and changes in the liver. The excessive administration of vitamin A to young rats and guinea pigs has been associated also with bone fragility and fractures.

Although in the human being the administration of up to 300,000 U.S.P. units of vitamin A daily for a number of months has not produced detectable harmful effects, some persons have developed sensitivity to cod liver oil. It is of interest that the ingestion of polar bear liver results in serious illness which is due to the large amount of vitamin A in polar bear liver at certain times of the year. Analysis of polar bear liver shows that it may contain as much as 18,000 I.U. of vitamin A per gram of wet material. Affected persons develop severe headaches and vomiting. Although some investigators have not accepted the idea that it is vitamin A which causes toxicity of polar bear liver, the author sees no reason to look beyond this. Hypervitaminosis A in its chronic form is characterized by anorexia, loss of weight, sparsity of hair, hepatomegaly and tenderness over the long bones which show characteristic roentgenographic changes occurring most frequently in the ulna and tibia. The changes consist of a parallel type of periosteal reaction, especially in the mid portion of the shafts with swelling of the overlying muscles and soft tissues. Calcified rings appear about the epiphyses.

**Hypervitaminosis D.** In 1928 and 1929 considerable interest was centered on the effect of administering repeated massive doses of vitamin D to experimental animals. In a study on normal animals, Kretzmar and Moll found that the administration of massive doses of irradiated ergosterol was followed by calcium deposition in some of the tissues. In a study of the effect of repeated large doses of irradiated ergosterol to experimental animals with either acute or chronic tuberculosis, Spies found extensive deposition of calcium salts within the caseous lesions. He also corroborated the findings of other workers who reported that massive and repeated dosage of vitamin D was followed by loss of weight, cachexia and calcification of many of the tissues. In addition he ob-

served an even more widespread calcification than had been reported previously and a retention of nitrogenous products in the blood which was associated with marked kidney lesions. When such toxic manifestations occurred in animals, the possible danger of giving repeated large doses in clinical practice was obvious.

In human beings hypercalcemia follows the repeated administration of large doses of vitamin D. Reed believes, however, that the toxic effects of vitamin D are independent of its action in raising the calcium and inorganic phosphorus concentration in the blood serum. Persons treated for a prolonged period of time with massive doses of vitamin may exhibit calcification of the soft tissues.

Frequently it is difficult to obtain a history of excessive vitamin D therapy, but in all cases of unexplained hypercalcemia the patient should be carefully questioned in regard to vitamin D therapy. This is particularly important should an operation for adenoma of the parathyroid gland be considered. According to Park, early symptoms of overdosage are nausea, headache, diarrhea, loss of appetite, frequent micturition, nocturia and lassitude. Examination of the urine may reveal evidence of overdosage. Albright and his collaborators noted that after enormous doses of vitamin D in a child with intractable rickets, the urine was loaded with calcium and contained many calcium casts such as have been observed in cases of hyperparathyroidism.

Two cases of hypercalcemia with calcification of soft tissues and renal damage have been reported by Danowski, Winkler and Peters. Bauer and Freyberg have reported a fatal case of vitamin D intoxication in an adult woman who received massive doses of vitamin D for over one year. At autopsy white chalky deposits of calcium salt were found in the myocardium, kidneys and arteriovascular system. In growing children there is a dense deposit of mineral in the zone of provisional calcification in the metaphyses of long bones in addition to metastatic calcium deposits in various organs and in and about joints.

Therapy with massive doses of vitamin D for very long periods of time demands careful supervision by the physician. Serum calcium should be determined frequently and at the first suggestion of hypercalcemia the dosage should be reduced. The patient should never be allowed to continue treatment on his own initiative. The greatest danger of all perhaps comes in taking

doses of vitamin D large enough to produce cumulative effects over a very long period of time. Once the diagnosis of hypervitaminosis D is made the patient should be prohibited everything which tends to increase the blood calcium.

## Snake Venom Poisoning

Venomous serpents are particularly abundant in tropical and subtropical countries which are under intensive agricultural cultivation. The ophidian population of such places is always augmented as a result of the increase in the number of rats mice and other rodents which accompanies the production of crops. India Java Malaya, southeastern Brazil southwestern United States eastern Mexico and the Central American republics since the advent of widespread cultivation may be cited among the highly snake infested regions of the world.

Venomous snakes feeding on rodents are rather rare in forests or in wooded districts even in the tropics because in order to survive they must resist active competition on the part of many species of predatory animals both birds and mammals which also feed on rodents and live in woody sections.

**Etiology.** From a biological point of view most serpents must be considered venomous for on each side of the head they have a gland that yields a viscous secretion capable of producing toxic or destructive effects on animal tissues. From a medical standpoint however only those ophidians are considered *veneniferous* which upon biting or stabbing are able to inject the secretion of their supralabial glands more

or less deeply into the tissues of their prey or potential enemy.

These snakes are all included in two groups which in ophiology are called Proteroglypha and Solenoglypha. The Proteroglypha bear small fangs longitudinally grooved one on each side of the anterior upper jaw each fang is firmly implanted in the maxilla which is articulated with other skull bones. The coral snakes are the only representatives of this group in America.

The Solenoglypha bear rather large fangs hollow like a hypodermic needle in a series on each anterior aspect of their upper jaw of each series the foremost fang is the acting one the others being supplementary. The ophidians of this group are the vipers which are of two kinds the more important being the pit vipers named after the hole or pit on each side of the head between the nostril and the eye. Among the true pitless vipers the most dreaded species is the Gaboon viper which is provided with very voluminous venom glands and large fangs. The pit vipers are found in the United States where they are represented by the copperhead the water moccasin and the rattlers of which there are some twelve species. Of the rattlers the most venomous are the Florida rattler the Texas rattler the prairie rattler and the black tailed rattler. In Latin America the most important pit vipers are the fer de lance or barba amarilla the cascabel or cascavel the surucucu or bushmaster the jararaca the jararacuçu and the urutu.

The venom apparatus is made up of a gland a duct and an active fang on each side. Physiologically the venom acts as a sort of saliva and serves both to facilitate the swallowing of the prey and to initiate the digestion of the prey's tissues through enzymic action. The amount of venom a serpent can eject varies from a few drops to 2 ml the active constituents may weigh as much as 650 mg (exceptionally 1 gm).

**Chemistry of Snake Venoms.** Venoms are composed chiefly of proteins including toxins and enzymes which are responsible for their toxicity. The toxicity of a venom may be lost if it is treated by chemicals or exposed to both light and heat. However venoms are little modified by glycerin which serves as the best means for their preservation in the field. In the laboratory full stability can be achieved only when the venom is frozen and desiccated under high vacuum immediately after being obtained.

from the snake and is subsequently kept in the dark and at low temperature \*

For many years little was known of the chemical composition and the real nature of the toxic principles of venom Professor Karl Slotta and his associates working at the Instituto Butantan under my direction have confirmed the findings of Micheel and Jung as to the chemical nature of the venom active principles and are inclined to ascribe to the presence of 5 to 7 atoms of sulfur (bound to cystine) an important binding role in the large protein molecule of the neurotoxin giving it a peculiar specificity Moreover they have succeeded in isolating from the South American rattlers venom an active principle crotoxin which contains 18 amino acids at least and has a molecular weight of about 30 500 Crotoxin exerts both neurotoxic and hemolytic actions in the body and appears to be composed of two pharmacologically different substances (Neumann and Habermann) Another principle called crotamin has recently been isolated from South American rattler venom From the venom of the Indian cobra a purified enzyme different from neurotoxin has been obtained in crystalline form it represents the hemolytic principle of this venom being about thirty three times more potent than the latter

According to Singer and Kearney the yellow color found in most venoms particularly those of the Nearctic rattlers and the Neotropical species of Bothrops seems to be due to riboflavin the action of which is correlated with the presence of an enzyme amino acid oxidase

**Pathological Physiology** Every venom appears to have unique properties The individual physiological peculiarities are due to the variations in composition which are found among species even of the same genus Thus the venom of the South American rattler *Crotalus terrificus* acts very slowly upon the organism and produces nervous symptoms (blindness local paralysis and so forth) only after an incubation period of a few hours and never causes even local pain The venom of nearly all the North American rattlers (*Crotalus atrox*, *adamanteus*, *ruber*, *molossus* and others) acts rather rapidly upon the body

\* From a biochemical standpoint the following powerful enzymes have already been recognized by electrophoresis in snake venoms serving both to complicate the action of the poison toxins and to induce harmful progressive chain effects on the tissue constituents proteases nucleotidases amino-acid oxidase hyaluronidase (spreading factor) phosphatases (including phospholipase A) and acetylcholinesterase

and causes marked swelling and other local symptoms in the virtual absence of any sign of nervous disturbances

The active constituents of snake venoms are usually classified as neurocytolysins hemolysins and hemocoagulins proteolysins and cytolysins

**Neurocytolysins** have a systemic effect are slow to act and affect the respiration and circulation or the vision and other specialized functions They are prevalent in the venom of the South American rattler and all the Western World coral snakes the Indian cobras the African mamba and others

**Hemolysins** acting on both the erythrocytes and the leukocytes complicate the local symptoms produced by proteolysins and cytolysins which act in the earlier stages of the poisoning and are responsible for the respiratory disturbances which sometimes appear during the later phases of the venenation By lysis of red cells hemolysins contribute to the reduction of the oxygen intake of the tissues They are particularly prevalent in the venom of the Indian cobra and daboia the Texas rattler the South American urutu and fer-de lance

**Hemocoagulins** act both on the coagulating and the anticoagulating mechanisms of the blood Some venoms have trypsin like enzymes and react with prothrombin to form thrombin while others bear papain like enzymes and react with fibrinogen to precipitate fibrin the result in both cases being blood coagulation In the former group may be included the venoms of the South American jararaca and fer de lance and some coral snakes in the latter group are the venoms not only of the Florida rattler and the South American cascabel but also of the South American jararaca and fer de lance Finally those venoms that prevent blood coagulation appear to destroy either prothrombin or fibrinogen or else they neutralize thrombin itself thus acting in the same manner as heparin This type of venom is secreted by such snakes as the American water moccasin the African puff adder the Texas rattler the Indian daboia and the European sand viper and a heparin like action is exerted by the Indian cobra venom

**Proteolysins** and **cytolysins** are the typical phlogogenous substances responsible for the local symptoms such as pain swelling discoloration necrosis and mutilation which follow the stab of certain vipers and pit vipers They are particularly noticeable in the secretion of such snakes as most North American rattlers the Latin Ameri

can fer-de lance jararaca jararacuçu and urutu the Japanese habu the Asiatic and Malayan green pit viper and the Indian daboia By dissolving the tissue proteins proteolysins open the way for cytolysons which in turn are responsible for the destruction of the cell structure

**Symptomatology** The symptoms of venation vary widely according to the chemical composition of the poison They may be briefly summarized as follows according to the species or groups of snakes

1 *Coral snakes* salivation and lacrimation depression and somnolence trembling and convulsions—all resulting from the action of the chemical constituents of the venom on the autonomic nervous system The poisoning may result in death

2 *South American rattler* impairment of vision or complete blindness paralysis of both eyelids and eyeballs paralysis of peripheral muscles (especially about the neck which acts as though it were broken)—all caused by the action of the chemical principles on the neuromuscular apparatus finally a lesion of the lower nephron with occasional hematuria Death is usually the outcome

3 *Spectacled cobra* salivation and vomiting hemorrhages and fall of blood pressure prostration blindness and somnolence dyspnea apnea and death—all caused by the effect of the venom on the blood and the autonomic nervous system

4 *King cobra* dyspnea polypnea profuse sweating and death resulting from the direct action of the venom on the central nervous system and the phrenic nerve endings

5 *North American rattlers* local pain edema and discoloration followed by ecchymoses and phlyctenules blood destruction all through the affected tissues prostration nausea vomiting or diarrhea following absorption of residues of both tissue and blood collapse and sometimes death

6 *Indian daboia* marked local swelling and tissue destruction profuse hemorrhages because of lack of blood clotting fall of blood pressure and collapse hematuria albuminuria anemia and emaciation sometimes resulting in death

7 *Latin American pit vipers* excluding the cascabel and the bushmaster extensive local reaction with edema ecchymosis and adenitis thirst and diarrhea hemorrhages of the eyes ears mouth intestines or kidneys prostration exhaustion followed sometimes by death The symptoms following the bite of the Japanese habu

and most of the Asiatic and Malayan pit vipers are more or less comparable to these

**Diagnosis** The diagnosis of a case of venation is based primarily on the capture or examination of the snake that caused the bite and secondarily on the description of its characteristics by the victim The physician being acquainted with the local ophiological fauna must examine the patient thoroughly in order to establish his diagnostic conclusion The specificity of the treatment to be applied depends on the correctness of his findings Final diagnosis will be based chiefly on the discovery of puncture marks at the site of the alleged bite

**Prognosis and Death Rate** The prognosis of snake poisoning is always grave when the patient is small or young when the amount of venom injected by the bite is large or when the snake fang happens to enter a vein thus forcing the poison directly into the circulation

It may happen that the serpent has recently eaten or bitten an animal before biting a human being In this instance little venom may be present in the glands and the accident will be mild In contrast the serpent may be fullgrown or may have been quiet for a long time in such circumstances its glands will contain a large amount of secretion For this reason snake poisoning is usually more severe in early spring when the reptiles start crawling out from their winter retreats

In the event that symptoms develop rapidly and the patient loses sight becomes unconscious or experiences a rapid fall in blood pressure the accident must be considered serious and the prognosis bad

The death rate depends directly upon the types of snakes prevailing in any region With species like the Latin American cascabel the Indian cobras and daboia and the African mamba whose venoms are extremely powerful or are secreted in amounts too great for human resistance the death rate is relatively high An average of 25 000 deaths occur annually in India from ophidic accidents the majority of which are due to the spectacled cobra In contrast there were but 14 fatal cases of poisoning in Europe all caused by local vipers from 1883 to 1892 In the Okinawan islands an annual average of about 225 persons used to be poisoned by the habu with a death rate of about 15 per cent

In this country statistics prepared by the Antivenin Institute of America seem to indicate that the yearly number of cases

of snake bite may amount to 2000 to 3000 the death rate varying from 10 to 35 per cent

**Treatment** The treatment of snake poisoning consists in the application of specific antivenins followed by additional measures when necessary if antivenins are unavailable local therapy should be applied

*Antivenins* are the only known agents capable of neutralizing venoms and arresting their harmful effects on the body. Injections of these specific serums may be made hypodermically intramuscularly or intravenously (the patient being properly prepared against allergic reactions) according to the seriousness of the case

If the antivenin can be given at once or within the first two hours after the bite about half the dose should be injected immediately around the wound in order to prevent local destruction of the tissues by venom of the phlogogenic type such as that of the American and Oriental pit vipers and the daboia. In late treated cases however this local application is not indicated. In such cases and always in those in which the symptoms are severe intravenous injection of the specific antivenin is strongly advised

As to dosage the physician must remember that the age or weight of the victim of the bite is an important factor. Its relation to the amount of serum is just the reverse of the usual rules for dosage. In the case of ophiotoxosis the concentration of venom per kilogram of body weight is relatively greater in young or light persons (or animals) than in adult or heavy persons. Therefore the smaller or lighter the person the greater and the more urgent the need for the antivenin. When there is reason to believe that the venom inoculated by the serpent was of unusually large quantity or whenever the symptoms develop quickly and in severe form as for instance in children it is advisable to start with a double dose and repeat it at short intervals if the previous dose has not caused an amelioration of the symptoms. For adults or heavy patients the usual dose is one to three syringes or ampules of 10 cc each. The serum to be given may be either of the liquid type kept in the icebox for preservation of its potency or of the lyophilized type in which case the powder is first dissolved in the usual way

In all cases the victim should be watched for three to five hours after every injection and if his condition has not markedly im-

proved within that time an additional injection should be made \*

*Special procedure to be carried out when ever specific serum or antivenin is not available*

1 Apply a ligature or tourniquet above the bite site. This should be applied tightly at first but must be partially released for a few seconds at five to ten minute intervals so as to maintain the necessary circulation in the limb. There is no particular advantage in making an incision or in applying permanganate of potassium in solution or crystals or any of the other chemical agents empirically recommended for this purpose. In fact it is advisable to avoid any further mutilation or injury that might facilitate the development of tetanus gas gangrene or secondary infection and thus complicate the patient's condition. Exception to this rule may be made only in those cases with large swelling and discoloration followed by severe general symptoms such as result from a bite by the Indian daboia or the majority of the North American rattlers. The venoms of these serpents are both hemolytic and noncoagulant and cause intense edema and extravasations of blood. The toxins absorbed by the lymph vessels and at the site of their inoculation form a poisonous substance (*lysocytin* due to the splitting action of phospholipase A on lecithin) from the extravasated blood. For this reason it is advisable in these particular instances to make a series of incisions around the puncture marks left by the snake and to apply strong suction by means of a hydraulic pump (a good vacuum rubber bulb pump may be used) attempting to extract the lysocytin together with the residues of destruction of both blood and tissues

2 Strychnine caffeine black coffee or strong tea may be given to the patient if symptoms of weakness and giddiness develop

\* Since some venoms particularly those causing local hard edema and late tissue destruction appear to act also through the so-called anti spreading factor (hyaluronic acid) which hinders the absorption of the antivenin given around the site of the bite it is advisable previous to injecting the specific serum to mix with its dose a certain amount (about 1 to 2 mg) of hyaluronidase and administer the mixture subcutaneously. In this case in order to prevent the rapid dissemination through out the system of the toxic derivatives of the venom held up by the swollen tissues it is necessary to take special precautions with the patient by giving him an extra dose of antivenin with ephedrine intravenously and by watching his heart and kidney functions

3 It is important to bear in mind that in late and severe cases complicated by profuse bleeding symptoms of liver injury, low blood pressure or dehydration rapid relief may sometimes be obtained from the intravenous administration of saline followed by glucose solution or Ringer sodium lactate solution.

**Prophylaxis** The consequences of venenation may be prevented in two ways: first by avoiding snake bites; second by properly treating the accident.

The prevention of snake bites may be achieved by wearing heavy shoes and leather leggings whenever one goes into a snake-infested district and by avoiding the use of the bare hands in climbing a rock or a ledge where snakes may be encountered.

## Food Poisoning

### INTRODUCTION

Food poisoning may occur from the ingestion of a diverse group of inciting agents. The literature contains records of many outbreaks of gastrointestinal illnesses in which the inciting agent given is in error. Some of the errors in the earlier reports were due to lack of knowledge concerning the inciting agents. For example, *Salmonella* organisms have been assigned as the cause of several outbreaks of food poisoning which were obviously due to staphylococci. The term "ptomaine poisoning" is still used in newspaper reports of outbreaks of food poisoning and unfortunately is occasionally used by the medical profession. This term came into use soon after the word was coined by the Italian toxicologist Selmi in 1870. Much

work has been done with toxic products extracted from foods and tested by parenteral injection into animals. Animals receiving injections of these materials frequently manifested shock and developed diarrhea and labored respiration preceding death. Many filtrates prepared from broth cultures of *Salmonella* bacilli are toxic when injected intravenously into rabbits and other experimental animals. The peculiar feature of this toxicity is that it is limited to parenteral injections—the same material often is without any effect when given by mouth. This situation also applies to the products of putrefaction among which are the amines. The "ptomaine" theory would never have gained prominence if experimental animals had reacted similarly to man when fed foods implicated in outbreaks of food poisoning. Perhaps the majority of so-called "ptomaine food poisoning" outbreaks may be attributed to staphylococci. There is abundant evidence to indicate that putrefied foods in the absence of food poisoning agents are without ill effect when ingested. It is well known for example that the Eskimo considers putrefied seal meat a delicacy.

**Food Allergy** Some persons are allergic to certain items of food which though wholesome to most people may act as poisons to those who are sensitized to them. One example is the case of the *Vicia faba* bean which is cultivated extensively in New York, New Jersey, Illinois and California and is a staple article of diet particularly with people of Italian extraction. Sensitization to the bean appears to be on a hereditary basis since in certain families every member for generations has been reported severely affected. Therefore susceptibility varies and certain persons after years of eating the beans with impunity may suffer a single severe attack and none subsequently. Illness may follow inhalation of pollen from the blossoming plant or within an hour after eating the beans. The illness is characterized by acute febrile anemia with jaundice, hematuria and hemoglobinuria.

A number of chemicals have been taken by mistake or accident and thus have been implicated in food poisoning. Usually illnesses from chemical poisoning occur within a few minutes to an hour or two after ingesting the chemical. The poisons include antimony, arsenic, barium carbonate, cadmium, sodium fluoride, lead methyl chloride, mercury, nitrates and zinc. Of this list, cadmium and sodium fluoride have been most commonly involved. If acid

of snake bite may amount to 2000 to 3000 the death rate varying from 10 to 35 per cent

**Treatment** The treatment of snake poisoning consists in the application of specific antivenins followed by additional measures when necessary if antivenins are unavailable local therapy should be applied

**Antivenins** are the only known agents capable of neutralizing venoms and arresting their harmful effects on the body. Injections of these specific serums may be made hypodermically intramuscularly or intravenously (the patient being properly prepared against allergic reactions) according to the seriousness of the case

If the antivenin can be given at once or within the first two hours after the bite about half the dose should be injected immediately around the wound in order to prevent local destruction of the tissues by venom of the phlogogenic type such as that of the American and Oriental pit vipers and the daboia. In late treated cases however this local application is not indicated. In such cases and always in those in which the symptoms are severe intravenous injection of the specific antivenin is strongly advised

As to dosage the physician must remember that the age or weight of the victim of the bite is an important factor. Its relation to the amount of serum is just the reverse of the usual rules for dosage. In the case of ophiotoxosis the concentration of venom per kilogram of body weight is relatively greater in young or light persons (or animals) than in adult or heavy persons. Therefore the smaller or lighter the person the greater and the more urgent the need for the antivenin. When there is reason to believe that the venom inoculated by the serpent was of unusually large quantity or whenever the symptoms develop quickly and in severe form as for instance in children it is advisable to start with a double dose and repeat it at short intervals if the previous dose has not caused an amelioration of the symptoms. For adults or heavy patients the usual dose is one to three syringes or ampules of 10 cc each. The serum to be given may be either of the liquid type kept in the icebox for preservation of its potency or of the lyophilized type in which case the powder is first dissolved in the usual way

In all cases the victim should be watched for three to five hours after every injection and if his condition has not markedly im-

proved within that time an additional injection should be made \*

*Special procedure to be carried out when ever specific serum or antivenin is not available*

1 Apply a ligature or tourniquet above the bite site. This should be applied tightly at first but must be partially released for a few seconds at five to ten minute intervals so as to maintain the necessary circulation in the limb. There is no particular advantage in making an incision or in applying permanganate of potassium in solution or crystals or any of the other chemical agents empirically recommended for this purpose. In fact it is advisable to avoid any further mutilation or injury that might facilitate the development of tetanus gas gangrene or secondary infection and thus complicate the patient's condition. Exception to this rule may be made only in those cases with large swelling and discoloration followed by severe general symptoms such as result from a bite by the Indian daboia or the majority of the North American rattlers. The venoms of these serpents are both hemolytic and noncoagulant and cause intense edema and extravasations of blood. The toxins absorbed by the lymph vessels and at the site of their inoculation form a poisonous substance (*lysocytin* due to the splitting action of phospholipase A on lecithin) from the extravasated blood. For this reason it is advisable in these particular instances to make a series of incisions around the puncture marks left by the snake and to apply strong suction by means of a hydraulic pump (a good vacuum rubber bulb pump may be used) attempting to extract the lysocytin together with the residues of destruction of both blood and tissues

2 Strychnine caffeine black coffee or strong tea may be given to the patient if symptoms of weakness and giddiness develop

\* Since some venoms particularly those causing local hard edema and late tissue destruction appear to act also through the so-called anti spreading factor (hyaluronic acid) which hinders the absorption of the antivenin given around the site of the bite it is advisable previous to injecting the specific serum to mix with its dose a certain amount (about 1 to 2 mg.) of hyaluronidase and administer the mixture subcutaneously. In this case in order to prevent the rapid dissemination throughout the system of the toxic derivatives of the venom held up by the swollen tissues it is necessary to take special precautions with the patient by giving him an extra dose of antivenin with ephedrine intravenously and by watching his heart and kidney functions

**toxin** There are five toxigenic types A, B, C, D and E. Of these five, three have been found to cause food poisoning in man, namely, types A, B and rarely E. The symptoms produced by all types of toxin are the same, but the antitoxin differs for each type. The toxin appears to interfere with the production of acetylcholine.

**Symptoms** In some but not all persons the central nervous system symptoms characteristic of botulism are preceded by an active digestive disturbance and vomiting. In general, nausea and vomiting occur in less than twenty-four hours and appear to bear some relation to the degree of spoilage and to the amount of incriminated food consumed. Although dehydration may develop early in some cases, constipation is present in the later stages of the disease. Typical symptoms usually appear in twelve to thirty-six hours. In many instances the earliest symptom is a peculiar lassitude or fatigue, sometimes associated with dizziness or headache and attributed to constipation. Double vision or diplopia may occur early. Photophobia, nystagmus and vertigo are occasionally recorded. Difficulty in swallowing and in speech is observed later in the disease. A sense of constriction of the throat is described occasionally. Usually the tongue is coated and swollen. Paralysis of the pharyngeal muscles occurs in fatal cases, and it is not uncommon for fluids to be regurgitated through the nose and mouth. The muscles in the neck are often weakened and there may be muscular incoordination. There is no retention of urine, although the amount secreted may be small, since patients cannot swallow and proper fluid balance is not maintained. The temperature is usually normal or subnormal. Bronchopneumonia may develop because of aspiration of mouth contents. The pulse may be normal but often becomes rapid in the later stages, even though the temperature remains normal. The respiration occasionally becomes irregular and Cheyne-Stokes breathing has been observed just before death. The blood pressure is usually normal and no abnormalities in type or number of blood cells have been found. Death results from respiratory failure. Life has often been sustained for several hours by artificial respiration. The Drinker respirator has been used in several cases but without success. The duration of illness in fatal cases is usually three to six days after ingestion of the poisonous food.

**Diagnosis** The diagnosis of botulism can usually be made from the symptoms. Con-

fusion has sometimes occurred in cases of chemical poisoning involving methyl chloride and sodium fluoride. In acute sodium fluoride poisoning, vomiting, abdominal pains and diarrhea are marked. The paralysis of certain groups of muscles (eye muscles, facial muscles, hand extensors and those of the lower extremities), contraction of the pupils and paresthesia in the extremities have led to confusion with botulism. In botulism the gastrointestinal symptoms are mild if present and the diplopia, aphonia and labored breathing are pronounced. Methyl chloride poisoning is characterized by progressive drowsiness, mental confusion, stupor, nausea, pain in the abdomen and vomiting. In severe cases convulsions and cyanosis alternating with coma have led to confusion with botulism. In botulism the sensorium is usually clear up to the time of death. In the majority of cases there is a history of ingestion of home-canned foods which frequently may have had a rancid or slightly putrefactive odor or taste. In the laboratory diagnosis, blood taken from patients occasionally may contain sufficient toxin to cause the death of mice into which 1 ml. of serum has been injected intraperitoneally. If the food has been discarded and fed to chickens, lumberneck may develop in the chickens, causing death. Suspected items of food should be sent to the laboratory and examined for toxin and/or the presence of *C. botulinum*. The toxin can be typed in the laboratory using the specific antitoxin.

**Prognosis** The mortality from botulism in the United States is approximately 65 per cent, but in Europe it is much lower. When a large dose of toxin is ingested, symptoms occur within a short time, usually less than twenty-four hours. In nonfatal cases the symptoms subside slowly and usually several weeks elapse before all residual signs of the disease have disappeared and recovery is complete.

**Treatment** The treatment of botulism is unsatisfactory. The sooner the disease is recognized, the better the opportunity for the physician to treat those more fortunate persons who have eaten less of the poisonous food and have not manifested symptoms early. Since the majority of cases are due to type A or B, it is advisable to give polyvalent antitoxin for these two types. In the presence of symptoms, antitoxin is frequently given too late for it cannot repair the damage already done to the patient by the toxin. Antitoxin should be given even though the disease is advanced in the hope of neutralizing any toxin which

foods are placed in cadmium plated utensils such as pitchers or ice trays in mechanical refrigerators sufficient cadmium is dissolved to cause abdominal cramping severe diarrhea and vomiting within fifteen to thirty minutes after eating or drinking the foods or beverages. Sodium fluoride is widely used to exterminate cockroaches from food establishments. Since it is a white powder it has frequently been mistaken for baking powder, soda or flour. Illness usually follows within a few minutes to two hours and is characterized by an acute poisoning—vomiting (often hemorrhagic) diffuse abdominal pains and diarrhea occur with great constancy convulsions tonic or clonic spasms of certain muscle groups paresis of certain groups of muscles (eye muscles facial muscles hand extensors and those of lower extremities) hiccup and contraction of pupils may occur. Paresthesia occasionally is present in extremities and has led to confusion with botulism. Arsenic lead and mercury poisoning are discussed at length elsewhere in this book under their respective titles.

Shellfish poisoning has occurred along the West Coast in central California with a sprinkling of severe outbreaks from Juneau, Alaska to southern California, the Gulf of California and Mexico. In the eastern part of North America it has been found due to shellfish from the Bay of Fundy. The illnesses have been traced to the food of the shellfish *Gonyaulax* in the cases on the West Coast to *Gonyaulax catenella*. Chemical studies have been made of the poison and some preparations have been made which have a toxicity greater than 1 MU per microgram. The MU is the amount of mussel poison which when dissolved in 1 ml of water and injected intraperitoneally into a 20 gm white mouse will cause death in fifteen minutes. Shellfish poisoning is characterized by respiratory paralysis. Symptoms vary from trembling about the lips to complete loss of power in the muscles of the neck. The illness develops within five to thirty minutes and longer after eating the poisoned mussels.

**Plant Poisons.** Of the more common poisonings due to plants, snakeroot poisoning, mushroom poisoning, ergotism and water hemlock poisoning may be mentioned. The most poisonous of the mushrooms is *Amanita phalloides*. It has been reported that two or three of these mushrooms may be sufficient to cause illness and death in the adult. A patient with mushroom poisoning has hypoglycemia which may be accompanied by convulsions, severe abdominal

pain, intense thirst, nausea, retching, vomiting and profuse watery evacuations. The illness occurs within six to fifteen hours after ingestion of the poisonous mushrooms. **Ergot poisoning** has occurred from eating rye meal or rye bread prepared from diseased rye containing a fungus *Claviceps purpurea* and may develop after several meals of diseased rye. The symptoms are drowsiness, headache, giddiness, painful cramps of the limbs and itching of the skin. In the more severe cases gangrene may occur involving especially the fingers and toes and occasionally the ears and nose. **Water hemlock poisoning** occurs when the leaves and roots of the water hemlock are eaten. The onset of illness comes one to two hours after ingestion and is characterized by nausea, vomiting and convulsions.

In all instances of poisoning it is important to recognize the type in order to prevent the occurrence of further cases. Often there is no specific treatment; the vomiting and diarrhea serve the useful purpose of eliminating the poison which is not already absorbed. Symptomatic treatment should be given and in the types of poisoning characterized by severe vomiting and diarrhea, parenteral fluids should be administered if dehydration and loss of electrolytes in the body have been excessive.

### BACTERIAL FOOD POISONING

Food poisoning from bacteria may be divided into two general categories. In the first, toxins are preformed in the food by the growth of microorganisms and the illnesses are due to the toxins and not to the ingested organisms. In the other category, the living organisms alone are responsible for the illnesses, filtrates or heated dead cultures being without effect.

#### PREFORMED TOXINS

##### BOTULISM

Today most outbreaks of botulism occur from the use of home canned foods. In the United States ten to fifteen outbreaks occur annually. The term "botulism" originated from the word *botulismus* meaning "sausage" and was coined by physicians in southern Germany in the beginning of the nineteenth century. The causative agent *Clostridium botulinum* is a large gram positive rod shaped organism which is an anaerobic spore former. The organism is a natural saprophyte and is commonly found in the soil. The spores are very heat resistant and in foods that are not properly processed they may germinate and produce

toxin There are five toxigenic types A B C D and E Of these five three have been found to cause food poisoning in man namely types A B and rarely E The symptoms produced by all types of toxin are the same but the antitoxin differs for each type The toxin appears to interfere with the production of acetylcholine

**Symptoms** In some but not all persons the central nervous system symptoms characteristic of botulism are preceded by an active digestive disturbance and vomiting In general nausea and vomiting occur in less than twenty four hours and appear to bear some relation to the degree of spoilage and to the amount of incriminated food consumed Although dehydration may develop early in some cases constipation is present in the later stages of the disease Typical symptoms usually appear in twelve to thirty six hours In many instances the earliest symptom is a peculiar lassitude or fatigue sometimes associated with dizziness or headache and attributed to constipation Double vision or diplopia may occur early Photophobia nystagmus and vertigo are occasionally recorded Difficulty in swallowing and in speech is observed later in the disease A sense of constriction of the throat is described occasionally Usually the tongue is coated and swollen Paralysis of the pharyngeal muscles occurs in fatal cases and it is not uncommon for fluids to be regurgitated through the nose and mouth The muscles in the neck are often weakened and there may be muscular incoordination There is no retention of urine although the amount secreted may be small since patients cannot swallow and proper fluid balance is not maintained The temperature is usually normal or subnormal Bronchopneumonia may develop because of aspiration of mouth contents The pulse may be normal but often becomes rapid in the later stages even though the temperature remains normal The respiration occasionally becomes irregular and Cheyne Stokes breathing has been observed just before death The blood pressure is usually normal and no abnormalities in type or number of blood cells have been found Death results from respiratory failure Life has often been sustained for several hours by artificial respiration The Drinker respirator has been used in several cases but without success The duration of illness in fatal cases is usually three to six days after ingestion of the poisonous food

**Diagnosis** The diagnosis of botulism can usually be made from the symptoms Con

**Plant Poisons.** Of the more common poisonings due to plants, snakeroot poisoning, mushroom poisoning, ergotism and water hemlock poisoning may be mentioned. The most poisonous of the mushrooms is *Amanita phalloides*. It has been reported that two or three of these mushrooms may be sufficient to cause illness and death in the adult. A patient with mushroom poisoning has hypoglycemia which may be accompanied by convulsions, severe abdominal

pain, intense thirst, nausea, retching, vomiting and profuse watery evacuations. The illness occurs within six to fifteen hours after ingestion of the poisonous mushrooms. *Ergot poisoning* has occurred from eating rye meal or rye bread prepared from diseased rye containing a fungus *Claviceps purpurea* and may develop after several meals of diseased rye. The symptoms are drowsiness, headache, giddiness, painful cramps of the limbs and itching of the skin. In the more severe cases gangrene may occur involving especially the fingers and toes and occasionally the ears and nose. *Water hemlock poisoning* occurs when the leaves and roots of the water hemlock are eaten. The onset of illness comes one to two hours after ingestion and is characterized by nausea, vomiting and convulsions.

In all instances of poisoning it is important to recognize the type in order to prevent the occurrence of further cases. Often there is no specific treatment; the vomiting and diarrhea serve the useful purpose of eliminating the poison which is not already absorbed. Symptomatic treatment should be given and in the types of poisoning characterized by severe vomiting and diarrhea, parenteral fluids should be administered if dehydration and loss of electrolytes in the body have been excessive.

## BACTERIAL FOOD POISONING

Food poisoning from bacteria may be divided into two general categories. In the first, toxins are preformed in the food by the growth of microorganisms and the illnesses are due to the toxins and not to the ingested organisms. In the other category the living organisms alone are responsible for the illnesses, filtrates or heated dead cultures being without effect.

### PREFORMED TOXINS

#### BOTULISM

Today most outbreaks of botulism occur from the use of home canned foods. In the United States ten to fifteen outbreaks occur annually. The term "botulism" originated from the word *botulismus* meaning a sausage and was coined by physicians in southern Germany in the beginning of the nineteenth century. The causative agent *Clostridium botulinum* is a large gram positive rod shaped organism which is an anaerobic spore former. The organism is a natural saprophyte and is commonly found in the soil. The spores are very heat resistant and in foods that are not properly processed they may germinate and produce

large numbers of the heat killed cocci are observed. Usually there is a history of the food having been kept at a warm temperature for a period of several hours before being cooked and served.

When individuals rather than groups of people are taken ill with symptoms resembling those of staphylococcal food poisoning it is important first to eliminate other possible causes of the illness such as gall bladder disease, appendicitis, certain forms of intestinal allergy, onset of infectious diseases and functional bowel distress associated with emotional upsets. Enterotoxin may be produced by staphylococci in the bodies of patients under treatment with large doses of broad spectrum antibiotics. The diagnosis of staphylococcal food poisoning must be seriously considered when several members of a family or a group suddenly become ill with symptoms of vomiting, diarrhea, abdominal cramps and prostration coming on within two and one half to three hours after a meal. Enteric infections caused by bacteria or viruses are not of the explosive nature characterizing staphylococcal food poisoning and the illnesses appear over a longer period of time.

**Prognosis.** In general the acute illness in staphylococcal food poisoning usually does not persist longer than five hours although anorexia and diarrhea may continue for several days after the acute attack. Fatalities are rare. A death occurred in one member of a family made ill by contaminated beef and in one outbreak two children three and four years old died within twenty four hours after each drank 250 ml of milk from a goat suffering from acute suppurative mastitis. Other deaths have been reported in young children and aged or debilitated persons.

**Treatment.** Vomiting and diarrhea are usually severe, therefore it is not necessary to empty the stomach with a stomach pump or to give cathartics to free the gastrointestinal tract of enterotoxin. Prostration occurs in severe cases and the blood pressure may fall precipitously. The symptoms of shock are due to loss of body fluids and electrolytes resulting in decreased circulating blood volume and should be corrected immediately by the administration of saline solutions parenterally. The amount of fluid to be given should be governed by the age of the patient and the severity of the vomiting and diarrhea. There is no specific drug or serum therapy.

**Prevention.** Since staphylococci are abundant in nature and commonly present in the secretions of the nose and throat and in

purulent lesions of the skin it is impossible to exclude them from foods exposed to the air. Staphylococci will grow in the presence of amounts of salt and sugars which are inhibitory to the common enteric bacilli. Because of this fact many foods which the housewife would regard as preserved might provide a good medium for staphylococci. When staphylococci grow in food there is no perceptible off flavor or taste to indicate their presence. It has been shown experimentally that enterotoxin is not formed in periods up to four weeks at temperatures maintained by the ordinary mechanical refrigerators even though other conditions necessary for enterotoxin production are fulfilled. Therefore at the present time the best control of staphylococcal food poisoning consists in adequate refrigeration of perishable foods.

#### LIVING ORGANISMS

##### SALMONELLA FOOD POISONING

Since Salmonella infections are discussed elsewhere in this book only brief reference will be made here to the role of Salmonella in food poisoning. Strains of Salmonella have long been associated with food poisoning and many theories have been proposed to implicate them as causative agents when bacteriological studies have been negative or inconclusive. An attempt has been made to explain some outbreaks on the basis that these organisms produce endotoxins which survive heat treatments that would destroy the living Salmonella. Most of the work with endotoxins involved parenteral injections into experimental animals. Human volunteers fed filtrates and heat killed cultures of Salmonella which are toxic by parenteral injections into animals have not become ill—only living organisms have caused illness in man. If symptoms are caused by endotoxins the living organisms undoubtedly must invade the tissue to by pass the natural barrier of the gastrointestinal tract. In Salmonella infections characterized by acute gastrointestinal disturbances the onset of symptoms may vary from seven to seventy two hours after contaminated food has been eaten.

#### MICROORGANISMS IN RELATION TO FOOD POISONING

Although the role of enterococci in food poisoning has not been clearly established a number of food poisoning outbreaks have been described involving specific items of food which contained per gram hundreds of

is not already fixed in the tissues. At least 50 000 units of antitoxin should be given intramuscularly after the patient has been tested for serum hypersensitivity and if necessary desensitized.

It is important that other measures be taken in addition to specific treatment with antitoxin. The fluid balance of the body should be maintained and in the presence of pharyngeal paralysis which occurs early fluids should be administered parenterally. The taking of fluids or food by mouth should be discouraged when pharyngeal paralysis is marked in order to avoid the danger of aspiration pneumonia. Saliva should be expectorated or aspirated from the throat in such cases. The patient should be kept quiet in restful surroundings and encouraged to avoid even the slightest unnecessary movement. In outbreaks of botulism involving several persons those who have only tasted the food or eaten sparingly of it usually do not exhibit symptoms until some time after those who have eaten generously of the poisonous food. In such cases antitoxin should prove of great prophylactic value.

#### STAPHYLOCOCCAL FOOD POISONING

**Definition.** Staphylococcal food poisoning also is caused by a toxin formed in the food before ingestion. In the United States it is probably the most common of all food poisonings. Since it is not a reportable disease the number of cases occurring annually is unknown. It is an ailment which involves most persons at one time or another during their lives and no great attention is paid to it unless large groups of people are attacked such as at banquets, encampments or in public institutions.

**Etiology.** Although the relation of staphylococci to foods implicated in this type of food poisoning has been known since 1884 staphylococcal food poisoning was not generally recognized until 1930. This failure to recognize the disease was due to the fact that when implicated foods and cultures made from them were fed to experimental animals no illness followed. Unfortunately man appears to be peculiarly susceptible to the poison although extremely potent preparations cause vomiting and diarrhea when fed to kittens and monkeys (*Macaca mulatta*). However portions of enterotoxin containing food which cause serious illness in man may be fed to these animals with out ill effect. Not all strains of staphylococci produce enterotoxin and it is probable that only a few of the total strains in nature have this property. The entero-

toxin has been shown to develop within as short a period as four to five hours when food is kept at 86° F. Unlike diphtheria, botulism and tetanus toxins it is relatively heat stable and has caused illness in a human volunteer after having been boiled for thirty minutes. A wide variety of foods have been implicated including milk, Cheddar cheese, ice cream, cream-filled bakery goods, rapid-cured hams, potato salad, dried beef, sausage, chicken, gravy, tongue, sandwiches, hollandaise sauce, liver sausage, pressed pickled beef, bread pudding and chicken salad.

**Symptoms.** Symptoms of staphylococcal food poisoning usually appear within about three hours although occasionally they developed one to six hours after ingestion of food containing enterotoxin. The incubation period is influenced by the amount of enterotoxin consumed and the susceptibility of the person. The first symptom observed is salivation which is subsequently followed by nausea, vomiting, retching, abdominal cramps, prostration and diarrhea. In severe cases blood and mucus have been observed in the stools and vomitus. In mild cases nausea and vomiting without diarrhea may occur or there may be cramps and diarrhea without vomiting. Muscular cramps, headache and sweating often occur when symptoms are moderately severe. In severe poisoning marked prostration accompanies the vomiting and diarrhea and symptoms of shock have been observed. A few fatal cases have occurred usually in the very young, the aged or the debilitated. As a rule the acute symptoms are of short duration and generally subside after five or six hours.

**Diagnosis.** The short interval of time between the eating of the incriminated food and the onset of symptoms is one of the most characteristic features of staphylococcal food poisoning. If a list of foods served at the previous meal is available the various food items can be tabulated for those made ill as well as those who were not ill. With such a list it is often possible to implicate one item of food as a common denominator. The suspected food should be sent to the laboratory for a bacteriological examination. Usually implicated foods contain enormous numbers of staphylococci. However it must be remembered that the enterotoxin is not destroyed by boiling. In some outbreaks the food item has been bacteriologically sterile although enterotoxin was present. In such instances if the food is smeared on slides, stained and examined microscopically

# Deficiency Diseases

## Introduction

Among primitive forms of life there are many species which live and grow on extremely simple diets. If they are endowed with photosynthetic capacity, carbon dioxide may serve as the sole required source of carbon. Many nonphotosynthesizing microorganisms require only a single organic compound such as glucose for their nutrition. Such forms are said to be *autotrophic* and for autotrophic bacteria there are no essential amino acids, no vitamins.

There is no evidence that the metabolic pathways in primitive autotrophs are any simpler than are the corresponding pathways in higher organisms. The same kind of array of nucleotides, amino acids, lipids and proteins can be demonstrated in the primitive forms of life as in the tissues of the mammalian organism. The difference is exemplified by the fact that niacin is synthesized by the autotroph at a rate compatible with its needs, whereas the *heterotrophic mammal has lost this ability* and must ingest niacin to replenish its supply of pyridine nucleotide required for survival.

The *heterotrophic state* i.e. the requirement for a complex diet if the organism is to survive and grow stems from the loss presumably by mutation of the capacity to synthesize from available dietary sources one or more necessary cellular ingredients. The occurrence of such mutations has repeatedly been observed especially in *Neurospora crassa* cultures of the autotrophic wild strain have upon irradiation been found to generate daughter cells which require one or another amino acid or vitamin for further growth. In many cases it has further been shown that the defect in such a vitamin requiring mutant results from the loss of a specific

enzyme activity present in the parental wild type which participates in the synthesis of the vitamin in question. The complex dietary requirements of man and other animals may be pictured as the results of mutations with consequent disappearance of certain enzyme-catalyzed reactions involved in the biosynthesis of what we call vitamins or essential amino acids. Stated in another way any important organic compound of animal tissue may become a vitamin when and if an animal loses the capacity to synthesize that compound or to synthesize it at the required rate. Thus scurvy and beriberi become inborn errors of metabolism "differing from other metabolic defects such as sickle cell anemia, galactosemia or alkaptonuria in two important regards. First the enzyme defects which result in beriberi or scurvy are universally present throughout the human species. Second the manifestations of disease are readily controlled by dietary supplementation.

In at least one instance the specific enzyme defect which leads to manifestations of disease when a vitamin is lacking in the diet has been pinpointed. Of the steps  $\text{D-glucose} \rightarrow \text{D-glucuronolactone} \rightarrow \text{L-glulonolactone} \rightarrow \text{L-ascorbic acid}$  over which ascorbate synthesis proceeds in the rat and many other species it is the last step which cannot be accomplished in man and in the guinea pig. Because of this absolute lack of a requisite enzyme, ascorbic acid becomes vitamin C for man and the guinea pig. In most other species including the rat, lack of ascorbic acid in the diet produces no disease and ascorbic acid is not a vitamin.

A somewhat different condition is seen in Addisonian anemia. Here the metabolic error is apparently not inborn but is none the less real. The symptoms and signs which result are readily controlled by ad-

millions of *Streptococcus faecalis* a normal inhabitant of the human intestine. Human volunteers fed either the item of food or cultures prepared from the food have in many instances had symptoms similar to those involved in the outbreaks. Filtrates or heat-killed cultures have failed to produce symptoms when fed to human volunteers. Many volunteers who were fed cultures which were under laboratory cultivation for long periods of time also have failed to become ill. Since *S. faecalis* has been shown to decarboxylate tyrosine leaving an appreciable amount of tyramine in the food, it was postulated that perhaps the tyramine was responsible for the symptoms. However, human volunteers who were fed tyramine in amounts as large as 1 gm have remained well. The symptoms of this type of food poisoning are generally mild and are characterized by nausea, sometimes vomiting, colicky pains and diarrhea developing within two to eighteen hours after the incriminated food has been eaten and usually subsiding within a few hours, thus requiring no specific treatment. In these

outbreaks a number of different types of foods have been involved, such as Vienna sausage, beef croquettes, turkey dressing, evaporated milk, dried eggs, Charlotte Russe, roast beef and ham bologna.

*Bacillus cereus* and *Clostridium perfringens* have been reported in outbreaks of food poisoning causing illnesses identical to that described for enterococci.

# Deficiency Diseases

## Introduction

Among primitive forms of life there are many species which live and grow on extremely simple diets. If they are endowed with photosynthetic capacity, carbon dioxide may serve as the sole required source of carbon. Many nonphotosynthesizing microorganisms require only a single organic compound such as glucose for their nutrition. Such forms are said to be autotrophic and for autotrophic bacteria there are no essential amino acids, no vitamins.

There is no evidence that the metabolic pathways in primitive autotrophs are any simpler than are the corresponding pathways in higher organisms. The same kind of array of nucleotides, amino acids, lipids and proteins can be demonstrated in the primitive forms of life as in the tissues of the mammalian organism. The difference is exemplified by the fact that niacin is synthesized by the autotroph at a rate compatible with its needs, whereas the heterotrophic mammal has lost this ability and must ingest niacin to replenish its supply of pyridine nucleotide required for survival.

The heterotrophic state, i.e., the requirement for a complex diet if the organism is to survive and grow, stems from the loss, presumably by mutation, of the capacity to synthesize from available dietary sources one or more necessary cellular ingredients. The occurrence of such mutations has repeatedly been observed especially in *Neurospora crassa* cultures of the autotrophic wild strain have upon irradiation been found to generate daughter cells which require one or another amino acid or vitamin for further growth. In many cases it has further been shown that the defect in such a vitamin requiring mutant results from the loss of a specific

enzyme activity present in the parental wild type which participates in the synthesis of the vitamin in question. The complex dietary requirements of man and other animals may be pictured as the results of mutations with consequent disappearance of certain enzyme-catalyzed reactions involved in the biosynthesis of what we call vitamins or essential amino acids. Stated in another way, any important organic compound of animal tissue may become a vitamin when and if an animal loses the capacity to synthesize that compound or to synthesize it at the required rate. Thus scurvy and beriberi become inborn errors of metabolism, differing from other metabolic defects such as sickle cell anemia, galactosemia or alkaptonuria in two important regards. First, the enzyme defects which result in beriberi or scurvy are universally present throughout the human species. Second, the manifestations of disease are readily controlled by dietary supplementation.

In at least one instance the specific enzyme defect which leads to manifestations of disease when a vitamin is lacking in the diet has been pinpointed. Of the steps  $D\text{-glucose} \rightarrow D\text{-glucuronolactone} \rightarrow L\text{-glulonolactone} \rightarrow L\text{-ascorbic acid}$  over which ascorbate synthesis proceeds in the rat and many other species, it is the last step which cannot be accomplished in man and in the guinea pig. Because of this absolute lack of a requisite enzyme, ascorbic acid becomes vitamin C for man and the guinea pig. In most other species, including the rat, lack of ascorbic acid in the diet produces no disease and ascorbic acid is not a vitamin.

A somewhat different condition is seen in Addisonian anemia. Here the metabolic error is apparently not inborn but is none the less real. The symptoms and signs which result are readily controlled by ad-

ministration of vitamin B<sub>1</sub>, suggesting that this disease may be classified as a deficiency state. It may be noted however that the patient diagnosed as having Addisonian anemia under proper control with vitamin B<sub>1</sub> still has his disease. The defect which makes this patient unusually dependent upon a supply of exogenous vitamin is still present and he is described as having Addisonian anemia in remission. Here the name of the disease attaches to the underlying defect not to the presence or absence of signs and symptoms. According to this convention the entire healthy human population could be described as having scurvy, beriberi, pellagra etc. all in remission.

The proper design of a human diet requires the consideration of a number of factors. Among these the total caloric requirement must be met. The ratio of carbohydrate to fat must exceed that level which will result in dietary ketosis. An adequate supply of nitrogenous materials in the form of proteins must be insured. In addition there are a number of requirements for specific elements or compounds which are listed in the accompanying table. These comprise some nine to thirteen elements, eight to ten amino acids and eleven to sixteen compounds which may be classified as vitamins. Included in this list are all the known organic compounds which are needed for survival and health of the mammal and for which no adequate synthetic routes are available in man.

Whereas the daily requirements for essential amino acids in man are measured in hundreds of milligrams or in grams, the corresponding requirements for the vitamins are measured in milligrams or in micrograms. From this fact it could be inferred that the vitamins, the so-called micronutrients, are not necessarily destroyed by the essential reactions wherein they participate; that their function is in some sense catalytic.

For some but not for all the vitamins important catalytic roles can be defined. Thiamine undergoes conversion to thiamine pyrophosphate which serves as a coenzyme in the oxidative decarboxylation of pyruvic acid as well as in the transketolase reaction. Riboflavin enters into flavin adenine dinucleotide and flavin mononucleotide, both of which are coenzymes for various essential electron transferring reactions. Pyridoxine contributes to pyridoxal phosphate, the coenzyme in numerous transamination reactions, whereas niacin is needed to generate diphosphopyridine

nucleotide and triphosphopyridine nucleotide the cofactors of the several dehydrogenases. Folic acid has been shown to participate coenzymatically in various biological transfers of formyl residues and pantothenic acid is an essential part of coenzyme A, an activating cofactor of the acetyl and other acyl groups. The best known function of vitamin A is not strictly catalytic but relates to the very economical cyclical process whereby radiant energy is transduced into a nerve impulse at the retina. For several of the vitamins specific chemical functions cannot be assigned at this time.

## Undernutrition

**Definition** As used here the term *under nutrition* means a state of nutritional deficiency predominantly of calories and protein. There may or may not be a deficiency of other nutrients. The term is not a fortunate one lacking specificity as to nutrient and degree of nutritional deficiency. Nevertheless the term has come to have rather wide acceptance as meaning calorie and protein deficiency disease primarily.

Although it is customary to distinguish between calorie deficiency and protein deficiency calorie deficiency disease is in effect protein deficiency. Experimentally protein deficiency can be produced by feeding either a protein-deficient diet or a diet inadequate in calories. In the latter the calorie deficiency leads to the burning of protein for fuel (energy) and even though the amount of protein is adequate as such the protein is diverted to combustion and becomes insufficient for the body's needs as protein. A deficiency of calories in the diet causes disease only when it causes too much body protein to be burned for energy. This occurs only after the fat stores have been consumed or nearly consumed. In a person of normal weight these stores will not be large and may be soon exhausted depending on the extent of calorie deficiency. In obese subjects the process is much longer (it is the basis of weight reduction). When fat is gone protein is next consumed. Injury and deficiency disease may be said to exist when more than the small reserve of body protein has been burned. Thus calorie deficiency disease becomes in effect protein deficiency disease. In practice the deficiency is usually mixed from the beginning.

**Etiology** Deficiencies of protein and calories result from an inadequate intake, absorption and utilization of food and are common in many diseases ranging from the psychoneuroses to gastrointestinal obstruction. Simple idiopathic starvation is only occasionally encountered.

However deficiencies in the intake of protein and calories though common enough in disease and injury are not the only cause of actual protein deficiency disease or undernutrition. Many kinds of injury and disease are accompanied by a spontaneous idiopathic negative nitrogen balance. This is occasioned by an excess urinary excretion of nitrogen apparently mediated by the action of adrenal cortical hormones. This excess secretion of nitrogen is independent of intake which is often

reduced in disease and injury and is apparently the result of tissue breakdown. In fact it may be impossible to match the excretion by increasing the intake i.e. to bring about nitrogen balance even when the intake is increased by artificial means to high levels. This fact has led some persons to conclude that the negative nitrogen balance is a beneficial or protective reaction to injury despite the untoward effects it causes. This is possibly true. Nevertheless there are many examples of reaction to disease primarily beneficial which when excessive become harmful and retard recovery.

The phenomenon just described is sometimes spoken of as the *catabolic* phase of reaction to injury or disease. It persists for a variable length of time and exists to a variable degree depending on a variety of factors. Even so simple a restriction as confinement to bed may produce this effect. The most striking and uncomplicated examples are seen in fractures of the long bones in previously healthy and well nourished persons or in severe burns. In these circumstances the negative nitrogen balance stands out as a sharply defined abnormality clearly related to the acute injury and without any background of disease or other apparent cause.

The reaction occurs in a variety of injuries and diseases in severe burns after major surgical operations especially those in which the peritoneum is opened with infections such as osteomyelitis, empyema and abscesses and with some infectious diseases such as typhoid fever and meningitis. In addition to the original reaction similar though usually less severe reactions may occur as the result of complications during the course of an illness. The changing of casts, secondary operations, the opening of abscesses and the occurrence of secondary or complicating infections or infectious disease all may be accompanied by a return or exaggeration and prolongation of the nitrogen deficit and hence a delay in the onset of the anabolic or recovery phase.

It is clear that in many instances the nitrogen deficit will be aggravated and increased by a diminished intake of proteins and calories. A number of factors are responsible for this diminished intake. After injury and in many diseases there is often a loss of appetite and hence a lessened intake of food. With this specific loss of appetite there are often the factors of unappetizing meals, poorly prepared and served, weakness, difficulties of recum-

FIG 49 Structural formulas of vitamins (continued)

It should be noted that for several of the vitamins some degree of biosynthetic capacity does exist within the human animal. This may reside in the bacteria of the gastrointestinal tract as is probably the case with vitamin K or within the tissues of the mammal proper as is the case with choline. The composition of the remainder of the diet may largely influence the nutritional need for certain vitamins. Thus in the presence of a plethora of methionine symptoms of choline deficiency cannot be induced. If the tryptophan content of the diet is high niacin can be synthesized at a rate compatible with survival and health. Appropriate solar radiation results in the conversion of 7 dehydrocholesterol, an abundant metabolic product in man, into vitamin D<sub>3</sub> and circumvents the need for vitamin D in the diet.

The nutritional requirements for all cells in the mammalian body are not identical. Thus it is possible for one tissue to supply some ingredient which is essential for the proper functioning of another tissue. Studies of the nutrients which must be supplied to certain tissue cultures derived from human material have revealed requirements not exhibited by intact man. An example of such a requirement is that for glutamine exhibited by cultures of HeLa cells.

In the absolute sense those coenzymes containing vitamin contributions are

neither more nor less important than are a variety of other coenzymes which can be totally synthesized in the body. Adenosine triphosphate which contains no vitamin residues is every bit as essential to normal cell function as is diphosphopyridine nucleotide. One may speculate that of the many mutations entailing the loss of one or another enzymic activity certain ones are lethal and others are compatible with life and reproduction. Among the lethal mutations are those involving loss of capacity to synthesize an essential tissue constituent not represented in the normal diet or required in a more continuous supply than is provided by three meals a day. When a mutation results in loss of ability to synthesize an essential cell constituent which can be adequately supplied in the diet a new vitamin is born.

concerned with enzymatic processes. Body reserves protect in the case of those nutrients for which there is a large storage capacity—vitamin A, for example. Forced feeding to prevent or minimize the calorie and protein deficit will of course expose the patient to deficiencies of those vitamins such as the B complex concerned with metabolic oxidative mechanisms unless natural vitamin-carrying foods are supplied. A good example of the need for supplement is parenteral feeding with glucose after operations.

One important exception to the general lack of vitamin and mineral deficiencies in undernutrition should be made, namely that relating to calcium. In a variety of traumas, excessive calcium excretion, mainly urinary, accompanies the excess secretion of nitrogen. If it is continued and sufficiently severe, there occurs an actual calcium deficiency represented by demineralization of the skeleton in varying degree, sometimes sufficient to result in pathological fractures. This loss, like that of nitrogen, can often be minimized but not always overcome by an increased intake of calcium. There is the added complication of urinary calculi formed because of the high concentration of calcium in the urine combined in some cases with relative immobility (confinement to bed). There is insufficient evidence, however, that added calcium in reasonable amounts in the diet increases to any significant degree the likelihood of stone formation.

**Diagnosis.** The diagnosis of undernutrition is on the whole easy; in fact, the condition can in many instances be anticipated and prevented—true preventive medicine.

A patient when seen by the physician should have an appraisal of the state of nutrition, the probable effects of the disease on his nutrition and what is needed for the prevention or treatment of nutritional disease. Often this will require only the usual history, physical examination and routine laboratory work, but special laboratory tests may be needed. For the patient who is injured or acquires an illness while in a normal state of nutrition, the need can be determined in general from the nature of the illness and its severity and probable duration, but complications and variations in the response of the patient and his cooperation may require modification from time to time. For instance, in fractures of the large bones or severe trauma, in serious burns and in most major surgical operations for acute dis-

eases, an immediate negative nitrogen balance and calorie deficit can be anticipated. This should be met by nitrogen and calorie intakes to overcome or minimize these deficiencies.

Weight is of course the earliest and at the same time simplest guide to undernutrition unless it is masked by edema. Losses below 10 per cent of calculated ideal body weight may in general be considered evidence of actual protein deficiency. However, in some circumstances obese persons may have protein deficiency without calorie deficiency or reduction of weight below the ideal level. Hypoproteinemia can be detected by determining the concentration of and total circulating plasma proteins. Ordinarily the determination of the total serum proteins by the simple specific gravity methods suffices as a general diagnostic test and guide, but the greater significance of the albumin fraction and the possibility that albumin is depressed while total proteins remain normal or near normal make it desirable to determine serum protein fractions when such a situation is suspected. Accurate nitrogen balance studies are not often needed in these patients. Edema, except in patients with complicating renal or cardiac disease, is nearly always related to the hypoproteinemia and is in itself a strong indication of protein deficiency. It should indicate the need for a serum protein determination. It must be emphasized that edema may mask actual loss of tissue. Retention of 10 pounds of water can occur without visible edema.

The diagnosis of other possible nutritional deficiencies is made in the usual manner. Knowledge of the situation should lead one to anticipate such possible deficiencies and be on the watch for them.

**Treatment.** In practice, two stages of the reaction to injury or disease can be rather sharply differentiated and differ in their practical management. The first is the initial period when only the metabolic disturbance is present and no nutritional deficiency disease has occurred. In this stage, there is the possibility of preventing or minimizing serious effects. The second stage is that in which a greater or lesser deficiency has developed.

The prevention and treatment of undernutrition are simple and easy in principle. No difficult, highly specialized or expensive techniques are necessary. With occasional exceptions, inexpensive materials may be used. But they do require close attention and supervision on the part of the physician, the nurse and other personnel as

bency and apparatus nausea vomiting and the mental changes of illness Unfortunately to these are often added indifference to nutritional problems on the part of the physician and nurse and even misconception and ignorance regarding the proper diet and nutrient requirements In some cases the nitrogen (protein) deficit is still further increased by loss of nitrogen from hemorrhage exudates transudates and discharge from wounds and burned surfaces from diarrhea and vomiting even from albuminuria when this is present

The catabolic phase just described is followed by an *anabolic* phase during which the nitrogen balance becomes positive (provided intake is adequate) nitrogen is retained and protein formed the tissues are restored and weight is regained It corresponds to the period of convalescence and recovery and is deficient or lacking in unfavorable circumstances

**Morbid Anatomy and Physiology** The effect of this negative nitrogen (and calorie) balance depends on its severity and duration and on the nutritional state of the patient As has already been stated it is ordinarily most severe in a previously healthy and well nourished person (for a given grade of injury) and curiously slight or absent in those already ill and poorly nourished as though the body lacked the ability to respond normally (and defensively?) to injury It should be remembered however that the latter group are already in a state comparable to the end stage of an initially well nourished group which has suffered from the full and severe effects of such a reaction The restorative if not the preventive treatment is therefore the same in both

The spontaneous result of the reaction represents a balance between the severity and duration of the reaction and the resistance (nutrition) of the patient If the process is mild and of short duration in a well nourished patient little harm is done Such would be the effect from a mild burn or minor fracture The body has a sufficient reserve of protein and calories (fat) to tide it over To say in such cases that nutritional deficiency disease is present would be incorrect However if the reaction is severe and prolonged is not limited by treatment and consumes the reserve resources of the body actual deficiency disease does occur Primarily it is a protein deficiency although other nutrients as will be shown later may be involved

Keys and his associates have well demonstrated experimentally the effects of this

deficiency without the complications of accompanying disease They may be described as illustrating the basic harmful results of such a deficiency These may be aggravated or complicated by the effects of the primary injury or illness

The principal outward manifestation of this undernutrition is loss of body weight at first slight and representing mostly loss of fat When it is more severe and of longer duration there is a loss of tissue protein revealed externally by atrophy of muscles There is however a concomitant loss of native protein from parenchymatous organs and the blood plasma This is easily demonstrable by measurements of heart size and is also clearly evident in the liver and other parenchymatous organs There are accompanying physiological changes such as weakness hypothermia bradycardia and lowered basal metabolism together with significant mental changes of a character resembling those of the psychoneuroses With the hypoproteinemia there may be edema which if severe is not necessarily confined to the legs Decubital ulcers are a common complication

There is evidence also that more subtle changes of a harmful nature may accompany this undernutrition such as interference with immune body formation and hence with resistance to infection (a notorious complication of debility) and with production of secretions and enzymes Besides interference with such specific defenses against infection there may be secondary infection and impaired healing of wounds related to impaired health of tissues resulting from edema

In the presence of disease many of these abnormalities that are clearly evidenced in uncomplicated experimental undernutrition are aggravated or modified Fever and infection may prevent bradycardia and elevate the metabolism The weakened heart may be enlarged instead of smaller Edema may be massive with effusions into the serous sacs and weight may fail to decrease or may even increase because of the dropsy

So far little has been said of a deficiency of other nutrients such as vitamins and minerals Deficiencies of these are relatively uncommon in the condition described here particularly in those who were in good health and nutrition before the onset of the particular disease or injury The reduction in calorie consumption and slowing of metabolic processes accompanying many disease states themselves tend to reduce requirements particularly of the vitamins

red blood cells plasma fluid and electrolytes. It is assumed in this discussion that such replacement of acute losses has been made. Occasionally however intravenous feeding is necessary for the maintenance or restoration of nutrition. For this purpose plasma or a solution of amino acids is used for nitrogen. Glucose and an emulsion of fat supply fuel. The recent availability for intravenous injection of emulsions of fat with their high caloric value makes it possible to maintain nitrogen equilibrium and caloric balance for relatively long periods. It also lessens the need for large amounts of fluid which might overtax a weak heart cause circulatory failure induce or exaggerate edema and even provoke pulmonary edema and secondary pneumonia. Electrolytes and supplements of other nutrients such as vitamins and minerals may be added as needed.

There are drawbacks to intravenous feeding however. The salt in solutions of amino acids may be undesirable. Thrombosis of the veins used for injection occurs and may interfere with prolonged feeding. Febrile reactions may occur. The psychological influence of eating is lacking. Therefore intravenous feeding particularly by itself should be used only after careful consideration of the need and suitability and for no longer than necessary. Supplements of other nutrients such as vitamins and minerals should be given when necessary.

Except perhaps in burned patients vitamins and minerals present little difficulty in previously healthy persons unless the illness is severe and prolonged and has resulted in severe undernutrition. Adequate amounts for maintenance should be assured if these amounts are not available in the food they should be provided as supplements. In particular provision should be made for adequate amounts of those vitamins directly concerned with cellular oxidations—thiamine, riboflavin and niacin—when patients are maintained on large intakes of pure carbohydrates such as glucose that carry with them no complementary vitamins. In parenteral administration somewhat larger doses of these vitamins should be given than are normally required because of greater excretion. In previously ill patients or those seen for the first time with nutritional deficiency disease an appraisal should be made of their status in respect to vitamins and minerals and adequate restorative and maintenance treatment should be instituted.

## Kwashiorkor

In infants and young children severe protein deficiency may produce the syndrome known as kwashiorkor. In classic or pure cases the deficiency is one of protein alone and the intake of calories usually from starchy foods low in protein is adequate. If a mild to moderate deficiency of calories exists with the protein deficiency the result may be marasmic kwashiorkor. A severe deficiency of both calories and protein produces the well known classic marasmus or starvation which differs in many respects from kwashiorkor.

Kwashiorkor was first described and is found to the greatest extent in undeveloped areas of the world mainly in the tropics and subtropics. Since it was first reported from Africa the disease has been reported from Central and South America, India, China, the Philippines, Fiji, Indonesia, Malaya, the Caribbean islands and in Hungary and Italy. Under proper conditions however it can occur anywhere. The disease is most prevalent in weanlings though it occurs in infants at breast presumably because of deficiencies in the mothers or nurse's milk. In tropical countries the disease is associated with the intake of characteristic native carbohydrate foods such as cassava, yams and sweet potatoes notably poor in protein. Where cereals such as rice and wheat are used the disease is less prevalent and less severe. Though it occurs in maize-eating areas there is no specific relation to the consumption of that cereal. Improvement following the simple provision of a complete

well as the whole hearted cooperation of the patient. Much help can be derived from the use of *standardized procedures or routines*, particularly in a hospital. However as always each patient will present an individual problem his requirements will differ as will his response and he will need individual attention. Routines can provide only the basic framework of the procedure within which adjustments must be made for each patient. Standardized regimens will indicate the amount and kind of food and route of administration. They will not assure its consumption. Finally it is to be remembered that too much food in early realimentation of the severely undernourished may be harmful.

A number of excellent diets for this purpose have recently been published. In general 3000 to 5000 calories and 120 to 150 gm of protein are necessary and advisable in the types of injury and disease in which possible undernutrition may develop. Experience has shown that in many cases it is not necessary or desirable and may be harmful to secure complete nitrogen equilibrium during the early and more marked stage of the catabolic reaction; the disadvantages and difficulties of attempting to supply huge amounts of protein outweighing the advantages. However sufficient protein and calories should be administered to provide a high intake of nitrogen overcome the calorie deficit and take full advantage of the beginning of the anabolic period which will probably be hastened by this treatment.

When possible this nourishment should be provided as ordinary food supplemented when necessary by special feedings. In general an attempt should be made to secure an intake of around 2500 calories and 90 to 100 gm of protein by ordinary meals. The additional requirements are met by supplements. These are most satisfactorily furnished as milk drinks composed of milk with added skim milk powder or prepared casein and glucose. A variety of satisfactory formulas have been devised. A typical one provides 28 gm of protein and 343 calories for each 240 ml. Therefore three such feedings will add 84 gm of protein and 1029 calories or a total of 160 to 180 gm of protein and 3500 calories if the regular meals are consumed.

A careful record of intake—calories and nitrogen—should be maintained in such patients and it can be assumed that if intakes of around 3500 to 4000 calories and 120 to 150 gm of protein are secured the nitrogen deficit will be abolished or

minimized in most cases. Losses beyond about 10 per cent of calculated ideal body weight should be avoided if losses exceed this figure a more careful determination of the nitrogen balance should be made. In burned patients particularly and in those with exudates draining sinuses dysentery and other causes of abnormal loss of protein a careful check of the probable balance must be made to determine the necessary intake which in some cases may be unusually large. For instance it has been calculated that an average sized man with a third degree burn of 50 per cent of his body surface may lose as much as 19.9 gm of nitrogen in twenty four hours from the burned surface equivalent to 124 gm of protein.

With patients who are already in a state of nutritional deficiency disease more strenuous treatment is necessary because the problem is one of replacement rather than prevention—the replacement of losses rather than maintenance of reserves. Furthermore speed is highly desirable and delay merely prolongs recovery and convalescence. Loss of weight and muscle atrophy with due consideration for edema are again the best general evidence of a state of deficient protein nutrition. Hypoproteinemia indicates a cause of edema and gives a rough index of the degree of protein loss from other body tissues and organs. It takes graduated up to as high as 5000 to 6000 calories or higher and 200 to 300 gm of protein may be required and be very effective in severe deficiencies.

In patients with nutritional disease already established and in some other circumstances the ordinary intake of food by mouth may be inadequate and tube or parenteral feeding may be necessary. It may also be necessary in delirious or mentally ill patients in those with disease of the gastrointestinal tract especially as a preoperative procedure when haste is necessary or desirable and for those who do not cooperate by ingesting adequate amounts of food. Often such feeding is best accomplished by stomach or duodenal tube which can be used intermittently or for a continuous drip. For this purpose a variety of formulas for liquid foods are available most of them similar to those used for supplemental feeding by mouth. In some cases it may be necessary to use intravenous feeding alone or in combination with gastric or duodenal gavage. Ordinarily such intravenous feeding is only for replacement of nutrients lost acutely such as in operations or trauma and includes

imbalance added potassium chloride is sufficient and may be given with the formula. In moderate and severe cases with marked dehydration buffered hypotonic solutions such as the Ringer lactate solution of Hartman may be given intravenously in doses of 40 to 50 ml per kg. Later Dennis solution may be given more slowly. Vomiting may alter the picture by the loss of hydrochloric acid. Close clinical observation as well as laboratory facilities to the extent available are necessary to combat complex derangements.

Other deficiencies as for example pellagra, beriberi and vitamin A deficiency should be treated adequately. In the marasmic form total calories must be adequate. Because susceptibility to infection is so great routine antimicrobial therapy is recommended.

### Vitamin A Deficiency

Vitamin A is an unsaturated cyclic alcohol soluble in fat solvents.

As far as is known the original source for all the vitamin A in all species of fish, birds and mammals is the carotenes and related carotenoids. Vitamin A occurs in the animal kingdom and is present chiefly in the liver although the kidney, lungs and fat droplets may contain some. For many years vitamin A<sub>1</sub> has been known to occur in sea fish oils and more recently vitamin A has been found in the oils of certain fresh water fish. The provitamins A are not ordinarily found in large quantities in the healthy person since they are transformed into vitamin A and utilized in that form. A low plasma vitamin A and a high plasma carotene content suggest a failure in liver function.

One of the chief functions of vitamin A

in the body is the maintenance of epithelial tissues. In the absence of vitamin A over a sufficient period of time the cells atrophy and some of the basal cells proliferate. This produces a picture of keratinized epithelium. This type of epithelium is susceptible to bacterial invasion. In the late stages severe infections of the eye, respiratory organs, genitourinary tract and mouth are likely to occur. Another function of vitamin A is its participation in the so-called "visual cycle." After prolonged deprivation of vitamin A impairment of vision may occur giving rise to a form of night blindness. Wolbach has brilliantly demonstrated that the skeletal growth of young rats is retarded by vitamin A deficiency. He showed that mechanical damage of the brain and spinal cord results from the continual growth of the central nervous system within its skeletal framework.

A deficiency of vitamin A can sometimes be detected by dark adaptation tests or by an examination of scrapings from the eye or from the vagina. There is no absolute correlation between the vitamin A content of the blood and biophotometer readings or examination of the scrapings from the epithelial surfaces or the general physical examination. The first symptom referable to the eyes is loss of visual acuity in dim light. This symptom occurs in various diseases affecting the eye and is not pathognomonic. It should be seriously considered however in a person whose diet has been deficient in vitamin A or in a patient who has cirrhosis of the liver, any generalized alimentary tract disease or nutritive failure. In the late stages the ocular disease is termed *xerophthalmia*. Prolonged mild deficiencies of vitamin A may lead to the development of Bitot's spots, gray triangular patches in the scleral conjunctiva produced by an accumulation of epithelial cells. These spots do not occur over the cornea and they do not ulcerate.

Within the past few years cutaneous lesions caused by a deficiency of vitamin A have been described. The earliest clinical skin change is simple dryness. The most characteristic skin lesions are the plugs which form in the hair follicles resulting in a rough dry skin known as hyperkeratosis (see Fig. 50). Follicular hyperkeratosis occurs typically on the extensor surfaces of the arms and thighs and tends in some ways to resemble so-called "goose flesh" in its appearance.

**Treatment.** Green leafy vegetables, all yellow vegetables and fruits supply vitamin A in the human diet. Vitamin A proper

protein in the diet (or amino acids) indicates protein deficiency as its cause

In the classic sugar baby form the infant fails to grow becomes at first irritable then apathetic anorectic and listless but irritable when aroused Edema develops first localized to feet and legs and in severe cases becomes anasarca Subcutaneous fat is often well retained

In marasmic kwashiorkor there is severe tissue wasting loss of subcutaneous fat and usually dehydration Fluid and electrolyte balance are disturbed to a degree and kind not seen in the wet or classic form In both the classic and marasmic forms there are disturbances in enzyme activity which are not present in simple marasmus

In children of the pigmented races particularly changes occur in the skin and hair which are characteristic though not universal They vary greatly in different areas and with different forms and degrees of severity of the disease In Negroes the skin and hair may take on a reddish cast which is one suggested explanation for the use of the name kwashiorkor one meaning of which is "red" The hair is often bleached dry and sparse In very acute cases these changes may not appear In the hair the dyspigmentation may be noted as a band or zone in children who have had the disease and recovered The skin in addition to dyspigmentation may appear pale and may exhibit darkened thickened patches on limbs and back which may desquamate leaving pink almost raw surfaces of a pellagroid appearance There may be generalized desquamation

As is nearly always true in nutritional deficiency disease other deficiencies are apt to complicate the picture Furthermore parasitic infestation and diseases such as malaria may coexist adding to the severity of the illness as well as confusing the clinical appearance They may also precipitate the appearance of the disease in borderline states of deficiency

Kwashiorkor resembles pellagra and has been confused with it Pellagra undoubtedly occurs with kwashiorkor but kwashiorkor occurs independently and is not a form of pellagra Coexisting beriberi vitamin A deficiency and tropical anemia have been observed

The most common abnormalities disclosed by laboratory tests are hypoproteinemia and electrolyte and fluid imbalance The most frequent and serious pathological change is a fatty liver The hypoproteinemia is characteristic and an almost constant feature It is essentially a hypoal-

buminemia with the globulins usually elevated the gamma globulins almost exclusively Blood urea is reduced as is total cholesterol Alkaline phosphatase cholinesterase amylase lipase and trypsin are reduced Anemia is not a characteristic of the disease itself but may be present from other causes

Fluid and electrolyte imbalance do not occur in the pure form In the marasmic type dehydration is common and is customarily associated with diarrhea In this situation the fluid imbalance is no different from that seen in other diarrheal disease However protein deficiency alone can produce a deficiency of potassium and an imbalance of other electrolytes with a concomitant shift in compartmental fluids

The pathological changes occur mainly in the liver though other changes such as atrophy of intrinsic and extrinsic musculature and of the heart as is found in marasmus would be expected The liver is nearly always involved usually enlarged with fatty infiltration cellular necrosis and fibrosis singly or in combination Fat may be present up to 30 per cent In late and severe cases the liver may be shrunken soft and excessively fatty The frequency of infantile (as well as adult) hepatic cirrhosis in regions where kwashiorkor is prevalent suggests a possible relation to the processes occurring in kwashiorkor Obviously other possible causes of cirrhosis such as infectious hepatitis exist

The mortality in severe forms of kwashiorkor is high up to 80 per cent With recognition of the nature of the disease the detection of early and mild cases and the excellent response to treatment if it can be provided the mortality should be less Treatment consists primarily of the administration of protein This is best given as milk but other proteins (soybean for example) can be employed Such treatment will be effective in most cases if irreversible changes have not taken place In those parts of the world in which the disease is most common local habits and customs may interfere with proper treatment Feeding may present great difficulties and infants may refuse to take other than their accustomed food However supplements can be provided in many ways When possible tube feeding may be employed and solutions of amino acids have been used with success Blood and plasma transfusions have been employed but are principally a temporary aid When electrolyte and water imbalances are present they should be corrected With mild electrolyte

imbalance added potassium chloride is sufficient and may be given with the formula. In moderate and severe cases with marked dehydration buffered hypotonic solutions such as the Ringer lactate solution of Hartman may be given intravenously in doses of 40 to 50 ml per kg. Later Dennis solution may be given more slowly. Vomiting may alter the picture by the loss of hydrochloric acid. Close clinical observation as well as laboratory facilities to the extent available are necessary to combat complex derangements.

Other deficiencies as for example pellagra, beriberi and vitamin A deficiency should be treated adequately. In the marasmic form total calories must be adequate. Because susceptibility to infection is so great routine antimicrobial therapy is recommended.

<sup>1</sup> The allowance levels are intended to cover individual variations among most normal persons as they live in the United States under usual environmental stresses. The recommended allowances can be obtained with a variety of common foods providing other nutrients for which human requirements have been less well defined.

<sup>2</sup> Niacin equivalents include dietary sources of the preformed vitamin and the precursor tryptophan. 60 milligrams tryptophan equals 1 milligram niacin.

<sup>3</sup> Calorie allowances apply to individuals usually engaged in moderate physical activity. For office workers or others in sedentary occupations they are excessive. Adjustments must be made for variations in body size, age, physical activity and

environmental temperature.

<sup>4</sup> The Board recognizes that human milk is the natural food for infants and feels that breast feeding is the best and desired procedure for meeting nutrient requirements in the first months of life. No allowances are stated for the first month of life. Breast feeding is particularly indicated during the first month when infants show handicaps in human milk due to different rates of maturation of digestive, excretory and endocrine functions. Recommendations are listed per liter of mother's milk as afforded by cows, milk formulas and supplementary foods given the infant when breast feeding is terminated. Allowances are not given for protein during infancy.

is supplied by milk liver and to a lesser extent by kidneys and animal fats A liberal supply of these foods in the diet is excellent prophylactic therapy Persons with night blindness xerophthalmia or keratomalacia can usually be relieved by ingestion of 5000 to 50 000 units of vitamin A daily in the form of synthetic vitamin A a potent fish liver oil or carotene The skin lesions may require doses of 50 000 units of vitamin A daily They respond slowly as a rule three to four months of therapy elapse before beneficial results are observed Carotene which is a precursor of vitamin A can be given in such large amounts that it causes a yellowish discoloration of the skin which often is confused with jaundice

## Vitamin B Deficiencies

### BERIBERI

**Definition** Beriberi is a clinical syndrome associated etiologically with a faulty food supply or an alteration of metabolism associated with thiamine deficiency It is characterized clinically by multiple neuritis serous effusions edema muscular atrophy and cardiovascular changes It occurs sporadically and endemically and passes in great waves over the Oriental countries The disease is associated with ignorance and poverty and may appear in any race and at any age

**History** Though the precise origin of the word beriberi is unknown the term undoubtedly arose from an Oriental language many centuries ago There is good reason to believe that the disease was described in the Niching (2697 B.C.) In 1642 Jacobus Bontius the first Occidental physician to describe the disease pointed out that the natives of Java called it beriberi During the nineteenth and twentieth centuries great interest arose in the recognition and prevention of beriberi and closely related

diseases During this period of renewed clinical interest investigators applied dietary methods of prevention to special groups of the population with great success

**Incidence** Beriberi occurs sporadically throughout the world It is prevalent both among infants and adults in the endemic areas of China Japan Indonesia Brazil India the Malay Peninsula and the Philippine Islands At times sudden outbreaks of the disease occur in these countries and in prisons and asylums of the Western World

Recent studies show that beriberi (nutritional peripheral neuritis) is much more prevalent in the Western Hemisphere than is commonly supposed Its incidence is high among pellagrins alcohol addicts and pregnant women It is frequently associated with organic disease and often coexists with other nutritional deficiencies

**Etiology** The results of clinical and experimental studies point to a definite relationship between an unbalanced diet abundant in decorticated cereals and the development of beriberi Such diets are known to be deficient in thiamine (Vitamin B<sub>1</sub>) The ingestion of excessive amounts of fish or molluscs sometimes causes foxes to develop a type of thiamine deficiency The enzyme thiaminase in the fish some way inactivates the thiamine so that symptoms may appear As far as we have been able to learn this mechanism has not produced a case of beriberi in man Although it has not been proved that one specific factor is the sole cause of the disease clinical and experimental studies leave no doubt that persons with beriberi are greatly benefited by vitamin B<sub>1</sub> therapy

It appears that man cannot synthesize thiamine nor can he store it to any great extent The length of time or the degree to which a deficiency must be present before clinical evidence of the disease appears is not known Clinical studies show that the depletion period is extremely variable ranging from a few weeks to months or years They show also that certain factors predispose to and precipitate the development of the disease Prominent among these are increased physical exercise fevers hyperthyroidism and other conditions which are accompanied by an increased metabolic rate pregnancy and lactation digestive disturbances and chronic debilitating diseases which cause improper ingestion assimilation or utilization of food

At the present time the precise manner in which a deficiency of thiamine operates

to produce the symptoms of beriberi is not understood. Cocarboxylase (thiamine pyrophosphate) has antineuritic properties and plays a prominent role in oxidation and reduction.

There is considerable evidence that other nutritional diseases often coexist with beriberi. Persons with beriberi frequently have a deficiency of nicotinic acid and riboflavin.

**Morbid Anatomy.** Postmortem examinations are of little value in making a diagnosis or in explaining the pathological physiology of the disease. The findings are not constant but the process in general is one of degeneration affecting especially the myocardium, the gastrointestinal tract and the nervous system. The most common gross findings are emaciation of the body and atrophy of the muscles, particularly in the legs. The body is often edematous; the heart is dilated and hypertrophied and serous effusions and chronic passive congestion of the viscera are commonly observed. Microscopic studies show diffuse edema in various tissues and degeneration of the involved nerves, muscles and myocardium. Degeneration of the nerves varies from slight alteration to complete degeneration of the myelin and axis cylinder. The affected muscles show a diffuse parenchymatous degeneration with loss of striations and hyaline and fatty changes. The cardiac muscle fibers are often fragmented and contain hyaline and fatty material. Postmortem findings in infants dying of beriberi are practically identical with those found in the adult. The degenerative changes in the nerves are however less striking in the infant.

**Symptoms.** Beriberi may be an acute or chronic disease. In the infant it is nearly always acute; in the adult it is nearly always chronic. The symptoms of infantile beriberi appear identical with those of the fulminating type in the adult. Infantile beriberi is characterized by a rapid onset with diminished urinary secretion, constipation, rigidity of the body and cyanosis. The child has a peculiar whine and cries most of the time. He is weak, has a rapid, irregular pulse, edema of the legs and usually dies suddenly or rapidly and completely cured by treatment.

In contrast, the onset in the adult is usually insidious and the prodromata are vague and general. Lassitude, general itching, dyspepsia, tachycardia, fatigue on exertion and tenderness of the muscles occur early. After a variable period of time the symptoms can be associated with degeneration of the nervous system, alteration of the

gastrointestinal tract, the presence of edema and serous effusions or enlargement and dilatation of the heart. When the disease affects chiefly the peripheral nerves it is commonly called the dry type, when it is especially characterized by acute cardiac symptoms it is known as the "fulminating type" and when it is associated primarily with edema and serous effusions it is referred to as the "wet type" (Fig. 53). Beriberi strikingly selects the vagi, the peripheral nerves of the extremities and the vasomotor system.

Not all symptoms are necessarily present in a given patient and the order of their appearance may vary. A patient with predominating cardiac symptoms may suddenly exhibit gastrointestinal symptoms such as anorexia for food, vomiting or diarrhea; the patient with gastrointestinal distress may suddenly display such myocardial symptoms as dyspnea, precordial pain and circulatory failure. Either or both of the foregoing types may have or may develop peripheral neuritis; conversely a patient with peripheral neuritis may have cardiorespiratory or gastrointestinal symptoms. Serous effusions and edema may precede, accompany or follow the cardiac, gastrointestinal or nervous symptoms.

The symptoms subside slowly in the adults who recover; many months may pass before there is a restoration of function; if indeed complete restoration ever does take place. Often after the active phase of the disease disappears, residual paralysis, muscular atrophy and cardiac enlargement remain for a long time.

**Nervous Symptoms.** The chronic cases have involvement of the nervous system. The early course is characterized by tingling of the hands and feet and by weakness of the legs. The clinical manifestations are caused by an ascending symmetrical peripheral neuritis. The deep reflexes of the extremities at first increase, later diminish and finally are absent. Tenderness in the calf muscles and sharply defined patches of anesthesia and numbness often appear early. This process affects particularly the extremities and sometimes the diaphragm, producing wasting of the muscles, contractures, ataxia, lack of coordination and dyspnea. Sensations of touch, pain and temperature are usually decreased but at times may be increased. Anxiety states and mental confusion are common manifestations.

**Cardiorespiratory Symptoms.** When the disease is characterized especially by cardiac symptoms (fulminating type) the

FIG 54 Muscular atrophy of the upper extremities in a beriberi patient with severe peripheral neuritis. Compare the wasting of all muscle groups in the arms with fairly normal muscles of the shoulder girdle and neck.

adult patient usually dies suddenly and without a history of prodromal symptoms. Occasionally however a person with gastro-intestinal and neurological symptoms suddenly suffers the fulminating type of the disease. The cardiac symptoms are always striking. The most common ones are palpitation, tachycardia, dyspnea, lowered blood pressure, cardiac murmurs, changes in the electrocardiogram and paralysis of the diaphragm associated with "high output failure." Before death there is nearly always cardiac enlargement and dilatation, pulmonary congestion, edema, cyanosis and vasomotor collapse.

**Digestive Symptoms.** Frequently there is nausea, vomiting and epigastric distress. These symptoms are especially prominent in the acute fulminating type and are often found with cardiac decompensation.

**Other Symptoms.** Edema is the most striking feature in many cases. It usually begins in the legs and may progress until the whole body becomes involved. Sometimes a typical case with the body bloated from anasarca appears emaciated after diuresis. Hydropericardium and effusions

into various serous cavities are common and a low serum protein can be demonstrated frequently. At times the organs of taste, smell, hearing and sight are involved. Libido decreases. Anemia may appear in the later stages of the disease.

**Diagnosis.** The typical case can be readily diagnosed by means of a reliable dietary history and by the presence of certain characteristic physical findings. Almost without exception the history reveals that adults who have beriberi have subsisted on a monotonous diet abundant in carbohydrates (chiefly milled rice, wheat or corn). The physical findings are an enlarged heart, peripheral neuritis, edema and tenderness and atrophy of the muscles. Infants who are restricted to the milk of women with beriberi usually acquire the disease during the first three months of life. The diagnosis is made on the following objective findings: constipation, diminution in the volume of urine, rigidity of the body, irritability, a rapid and irregular pulse, weakness, edema, cyanosis and a peculiar whine.

Though the atypical or mild cases occurring in infancy or later are probably more common than the typical ones, the manifestations in such cases vary greatly and the disease is not easily recognized. Since there is no specific laboratory test for beriberi, it is often necessary to exclude the possibility of various types of heart disease, diphtheria, nephritis, tabes, alcoholism, lead and arsenic poisoning, pellagra, scurvy and sprue before a positive diagnosis of beriberi can be made.

**Prognosis.** No disease requires more conservatism in making a favorable prognosis than does beriberi. For a patient who seems to be recovering may suddenly exhibit cardiac symptoms and die. The mortality rate is variable, being around 5 per cent in the mild cases and reaching well over 50 per cent in the more severe ones. The ultimate prognosis is dependent upon the age and general condition of the patient and upon the severity and duration of the disease. In general, patients with acute cardiac symptoms are least likely to survive. If the adult is left untreated eventually incapacitation or even death is to be expected. If however the disease is recognized and treated early the outlook is good, provided the patient can and will follow recommendations. Recovery is rapid and complete in infants who are given early and persistent treatment.

**Treatment.** Crystalline vitamin B<sub>1</sub> (thia

mine hydrochloride) is recommended for every case in which the diagnosis of beriberi is established. It may be administered intravenously, intramuscularly or orally. Parenteral administration is recommended in severely ill cases, especially when thiamine deficiency is associated with severe gastroenteric disturbances or with cardiac failure. In such cases 30 to 50 mg should be given intravenously in sterile physiological saline twice daily. For the average cases the parenteral administration of 10 mg twice daily is adequate. Oral administration of 5 to 10 mg twice daily is sufficient for the mild case. Brewers yeast, wheat germ and tikitiki (an alcoholic extract of rice polishings) are effective therapeutic agents in the average case of thiamine deficiency. The usual dose of brewers yeast and wheat germ is 5 ounces and of tikitiki 3 ounces. The yeast and wheat germ are best tolerated if given in iced milk or eggnog at frequent intervals. All persons who have a thiamine deficiency should be given a well balanced, high caloric diet including foods rich in vitamin B<sub>1</sub>. These foods are whole grain bread and cereals, legumes, lean pork, liver, heart, kidney and milk. All patients, whether the disease is mild or severe, should be kept at complete rest until convalescence is well established.

For infants with beriberi the parenteral administration of 5 to 10 mg of crystalline vitamin B<sub>1</sub> is recommended. After convalescence is established the same amount may be administered orally. If crystalline vitamin B<sub>1</sub> cannot be procured an alcoholic extract of 100 gm of rice polishings (tikitiki) may be given daily. If the child's mother has latent or manifest beriberi, cow's milk should replace breast milk.

**Prevention.** Prevention in the adult or infant is dependent upon the ingestion of a sufficient amount and utilization of sufficient quantities of a well balanced diet. The most logical means of ending beriberi as a world problem in the near future would be to pass and enforce a law preventing the overmilling of rice, wheat and corn. Grain products have long been the principal component of the poor man's diet. Overmilling of the cereals has deprived the finished product of much of its natural mineral and vitamin content. Consequently the foods which may constitute the major part of the diet of persons most in need of improvement in their nutritional status are nutritionally inferior. The enrichment of flour and bread in this country is a step forward in improving the diets of these persons. Until such time as proper diets are available to all

people or until a law prohibiting the sale of overmilled cereals is passed and enforced, the incidence of beriberi can be greatly decreased by the application of the following recommendations:

1. Whole grain or enriched flour and bread should be substituted for the highly milled products.

2. Foods must not be overcooked since excessive heat destroys vitamin B<sub>1</sub>. The common habit of adding soda during the cooking process is detrimental and should be discontinued. Foods should be cooked in as little water as possible and the water in which they are cooked should be used in soups or broths rather than discarded.

3. Lean meat, milk, eggs, fresh vegetables, dried vegetables and nuts should make up at least 50 per cent of the daily diet.

4. Any one of the following relatively inexpensive supplements is helpful in preventing beriberi and should be added to the daily diet whenever possible: dried brewers yeast (1 ounce), wheat germ (2 ounces) or tikitiki (1 ounce). Infants are given indirect protection by preventing the disease in mothers and can be given additional protection by supplementing their daily diet with an alcoholic extract of 40 gm of rice polishings (tikitiki).

## PELLAGRA

**Definition.** Pellagra is a noncontagious, nonhereditary clinical syndrome affecting the skin, alimentary tract and nervous system. It is characterized by seasonal recurrences and relapses, may occur in any race and at any age and is associated with deficiency in niacin and other factors in nutrition.

**History.** The term "pellagra" from the Italian "pelle agra" meaning rough skin, was first used in

medical literature in 1771 by the Italian physician Frapolli who found the word in common use among the peasant population of Lombardy. The authentic history of the disease begins somewhat earlier in northern Spain. In 1735 Gaspar Casal, physician to King Philip V, recorded his observations on *mal de la rosa*, a malady prevalent among the peasantry in the province of Asturias. Twenty years later Antonio Pujati reported its presence in northern Italy, and in 1784 a special hospital for the treatment of pellagrins was established at Legano by warrant of Joseph II of Austria. During the nineteenth century the disease was observed in many other countries, chiefly in France, Egypt, and Rumania. In the United States, sporadic cases had been reported as early as 1864 from New York and Massachusetts, but it was not until 1907 when Searcy called attention to the presence of a large number of cases of endemic pellagra in an asylum in Alabama, that the seriousness of the situation in the southern part of the United States was appreciated. Within the next few years many cases were reported from practically all southern and from many northern States.

**Incidence.** Pellagra formerly was prevalent in many countries. The incidence was high in Egypt, the United States, Rumania, Serbia, Bulgaria, Russia, Italy, and Spain. Wilson stated that 30 per cent of the population of Egypt was affected with pellagra, and the United States Public Health Service estimated that there were 400,000 cases annually in the United States. It was believed that at least 10 per cent of the inmates of the insane asylums in the southern part of the United States were admitted because of pellagra. Owing to the use of nicotinic acid, pellagra has virtually been eradicated from the United States and greatly decreased in other countries.

**Etiology.** For many years opinion in regard to the cause of pellagra was divided. At the present time the opinion is accepted that pellagra is a clinical syndrome caused primarily by a nutritional deficiency which may arise in one or more of the following ways: (1) The person's diet may be inadequate in the antipellagic foods; (2) His absorption may be impaired because of altered gastrointestinal function; (3) His requirement for the antipellagic substances may be in excess of the amount supplied by a liberal well-balanced diet.

Goldberger advanced the theory that the pellagra preventive factor is a single substance, vitamin B (G), the thermostable portion of the vitamin B complex, and until recently many students of nutrition accepted this theory. It is now known that what he termed vitamin B is not a single substance for it is composed of a number of active principles. Four of the most important are niacin, pantothenic acid, pyridoxine, and riboflavin. It has been shown that niacin is a specific curative agent for

the mucous membrane lesions for many of the symptoms arising from the alimentary tract and for the mental symptoms of human pellagra, and that it aids in preventing recurrences of these symptoms. Its relationship to the dermatitis of pellagra has been fully established. After the administration of nicotinic acid, the concentration of coenzymes I and II in the blood and urine of pellagrins is increased from subnormal to normal values. The increase in concentration of these coenzymes, which are fundamental to cell respiration, parallels the clinical improvement of the patient. Recent work has shown that tryptophan when given in large amounts promotes relief of symptoms in pellagrins.

Certain predisposing and precipitating factors often play a role in the pathogenesis of the disease. Important among these are fatigue, insomnia, loss of teeth, infections, food idiosyncrasies, chronic alcoholism, and diseases which cause improper ingestion, assimilation, or utilization of food. Failure to consider all these conditions as underlying factors in the cause of pellagra has led to the designation of certain cases as "pseudopellagra," pellagra sine pellagra, postalcoholic dermatitis, alcoholic pellagra, and "secondary pellagra." Such terms are confusing and should be abandoned; the disease is or is not pellagra.

From 1937 to 1945 we studied over 10,000 pellagrins who ingested inadequate diets. We learned that pellagra usually coexists with beriberi, riboflavin deficiency, and other dietary deficiencies. The diagnosis of pellagra therefore necessitates a thorough search for evidence of other deficiency syndromes and the institution of therapy specific for each deficiency.

**Morbid Anatomy.** The most common gross findings are generalized emaciation of the body and atrophy of various organs. Pellagra can be diagnosed at the post mortem table only when the characteristic oral and skin lesions persist. In some cases the walls of the gastrointestinal tract may show swelling, reddening, and ulceration of any portion; in other cases the walls may be thin and atrophic. The liver occasionally contains abnormal amounts of fat. Histologically the skin lesions vary from atrophy to an intensive inflammatory reaction. Similarly, the microscopic picture of the intestinal lesions varies from atrophy to acute inflammation characterized by fibrin formation and collections of inflammatory cells. When changes in the nervous system are demonstrable, they are characterized by irregular areas of degeneration, often in

volving the posterior and lateral columns of the spinal cord the posterior spinal ganglia and the Betz and Purkinje cells

**Symptoms** These arise chiefly from the skin gastrointestinal tract and nervous system. They vary greatly with each patient arising in some from only one of the systems and in others from two or more.

**Prodromal Symptoms** The onset of pellagra is often so gradual that the earliest symptoms may not be noticed by the patient. Early in the disease there is a loss of strength particularly in the legs, a change in appetite and usually though not always a decrease in body weight. There may be also a change in mood or personality. Pellagra in the early stages of the disease is often incorrectly diagnosed as neurasthenia.

**Skin** Pellagrous dermatitis is not always present but when observed may be readily diagnosed by its appearance, symmetry, location and course. Symmetrical lesions may appear on any part of the body but are most common over sites of irritation such as the hands, wrists, elbows, neck, under the breasts, knees, feet and in the perineal region. A sharp line of demarcation at the periphery of the lesion separates the affected area from the healthy skin. In the majority of cases pellagrous dermatitis is restricted to the exposed parts of the body and the dermal lesions of pellagra often appear after exposure to sun light. The dermatitis begins as an erythema resembling sunburn. As the disease progresses the area becomes reddish brown, roughened, scaly and keratotic vesicles and bullae may form. Desquamation usually begins at the center of the lesion and the underlying skin appears red and thickened. The intensity of the pigmentation and the thickening of the skin tend to increase with each recurrence of the disease; after repeated recurrences the skin may become either permanently pigmented, thick and roughened or thin and atrophic (see Figs 58, 59, 60, 61).

**Alimentary Tract** Both glossitis and stomatitis are early and common symptoms and are usually such as to be diagnostic of the disease. In the beginning only the tip and lateral margins of the tongue are swollen and reddened (Fig. 57). If treatment is not given the swelling increases, the red discoloration becomes more intense and deeply penetrating ulcers may appear along the sides and tip—rarely on top. Frequently a thick gray membrane filled with debris and Vincent's organisms covers the surface. The tongue is usually

hypesthetic though it may be hypersensitive. The buccal membranes, the mucocutaneous surface of the lips, the gums and the palate may likewise be affected. The course of the stomatitis is similar to that of the glossitis. A burning sensation of the tongue and of the mucous membranes of the pharynx, esophagus and stomach is not uncommon. This is often aggravated by hot or acid foods. Ptyalism, nausea and vomiting may occur early but as a rule these are advanced symptoms of the disease. About 50 per cent of pellagrins have no free hydrochloric acid even after histamine stimulation; rennin and pepsinogen are likewise absent. Thus achylia gastrica tends to persist during remissions. The stools may be hard, soft or watery but the odor is invariably foul. Contrary to what is generally taught, the bowels in the majority of mild cases act normally or are constipated. Severe, persistent diarrhea with several watery stools each hour tends to appear only in the more acute cases. Abdominal distention, discomfort and pain may be present at any time during the course of the disease but are more severe after a large meal.

**Nervous System** Nervous symptoms are common but at the onset of the disease are often vague and ill defined. The patient may complain of nervousness, insomnia, headaches, dizziness, muscular weakness and a bilateral burning of the hands, feet and other parts of the body. The tendon reflexes are frequently altered. At first they may be exaggerated, later decreased, finally they may be absent. The extremities particularly the legs may "feel numb" or become paralyzed. Typical subacute combined degeneration of the spinal cord with spasticity and ataxia is found. Tremor and a spastic or ataxic gait are often associated with peripheral neuritis in the advanced cases.

**Mental Changes** Pellagrins are subject to periods of depression and apprehension and unless treatment is administered hallucinations, confusion, delirium and complete disorientation may develop. Tremor, jerky movements and rigidity of the body frequently accompany these mental symptoms. If such cases are given early and intensive treatment the mental symptoms seldom persist but in the absence of treatment the patient is likely to become psychotic.

**Organs of Special Sense** Any of the organs of special sense may be affected; loss of taste and smell is common.

**Gentourinary System** Burning on urina-

FIG. 60 Symmetrical exfoliating lesions on elbows and dorsal surface of the hands of a pellagrin in relapse. Multiple areas of ulceration and a few large bullae can be seen.

tion occurs frequently. Libido is often decreased. Sterility is unlikely. In the female acute pellagrous vaginitis with Vincent's infection is a usual finding. Menstruation may be scanty or absent.

**Circulatory System.** In the mild case a slightly subnormal blood pressure is often noted. In the severe case there is an increased pulse rate, lowered blood pressure and vasomotor collapse. Syncope and sudden death frequently occur.

**Blood.** The hemoglobin is less than 70 per cent in the majority of patients with severe pellagra. The anemia is either macrocytic or microcytic in type.

**Temperature.** The temperature of the mild uncomplicated case is usually normal. An elevation of several degrees is serious, since it denotes the presence of an infection or a severe type of the disease.

**Diagnosis.** The typical case is easily diagnosed on the basis of a reliable history and careful physical examination. The history is usually one of an inadequate or unbalanced diet, high in carbohydrate and fat content. Physical examination reveals the characteristic dermal and lingual lesions.

Atypical cases are many and can be recognized only by careful clinical study, since there is no specific laboratory test for pellagra. Were it not for the skin and oral changes characteristic of pellagra, neither the typical nor the borderline cases could be distinguished from cases of chronic alcoholism, beriberi, pernicious anemia or sprue.

**Prognosis.** Pellagra is always a serious disease. A favorable course depends on an early diagnosis followed immediately by intensive and persistent treatment. If untreated or incompletely treated, it usually becomes chronic and continues through remissions and recurrences until either the pellagra itself or a coexistent or resultant secondary disease produces incapacitation or death. The disease tends to increase in severity with each attack, but the author has observed recovery after thirteen distinct relapses. Even in cases with rare recurrences, the daily life of the patient must be properly regulated or he will fail to make satisfactory progress. Without special treatment, the death rate is more than 50 per cent in the severe cases. Once the disease mild or severe has remitted, the prognosis is good if no other predisposing condition or organic disease is present and provided the patient is cooperative and has perseverance to continue treatment.

Pellagrins who seem to be making satisfactory progress often become suddenly worse and die. No single manifestation can be used as the sole indicator of the prognosis. In each case the immediate outlook is contingent upon the general condition of the pellagrin and upon the presence or absence of other diseases.

The outlook is most grave when severe mental symptoms, hallucinations, violent motor excitement, opisthotonos, delirium, rigidity, tremors, ankle clonus, Babinski's sign or convulsions are present. Extensive and severe gastrointestinal symptoms, such as intractable diarrhea and vomiting, severe glossitis, stomatitis and cachexia may also have an unfavorable effect on the course of the disease. Refusal of food, long-continued abdominal distention and marked anemia should be regarded as ominous signs. Pellagra is not usually accompanied by fever; a temperature of 103° F. makes for an unfavorable prognosis. The danger is increased if chronic addiction to alcohol, fatigue or surgical operations intervene. The presence of infection darkens the outlook for just as infectious diseases predispose to pellagra, so are pellagrins unusually susceptible to infections.

**Treatment** Pellagra is a systemic disease and must be treated as such early promptly intensively and persistently. The essence of successful treatment is improved nutrition, adequate rest and good medical and nursing care. The methods must be adapted to the special needs of each patient and can be carried out most effectively if the patient is hospitalized and placed under the direct supervision of a physician assisted by a nurse and a dietitian.

**Treatment of the Mild Case** Every adult with mild pellagra must ingest and retain a well balanced high protein diet of at least 4000 calories per day; the diet should include 1500 ml of sweet milk,  $\frac{1}{2}$  pound of lean meat or liver and eight eggs. Additional milk should be given instead of water except in very dehydrated cases. Water tends to decrease the amount of food ingested; the milk will not only supply fluid but will also be an additional source of nourishment. Diets abnormally high in carbohydrate or fat content are contraindicated. The diet should be supplemented especially at night by large amounts of a potent specific therapeutic agent prepared by a reputable concern. When administered by mouth, dry powdered brewers' yeast (30 gm three times daily), wheat germ (60 gm three times daily), crude liver extract (30 gm three times daily) or niacin or niacinamide (10 doses 50 mg each daily) is effective. The amide is preferable to niacin when one wishes to avoid vasodilating reactions.

**Treatment of the Severe Case** The severe case that is one with central nervous system involvement, intractable diarrhea, persistent vomiting, marked anemia, a pulse rate exceeding 120 or a temperature of 103° F, must have immediate supportive as well as antipellagric therapy. As in the mild case, success of treatment depends upon improved nutrition, adequate rest and appropriate medical and nursing care. The food intake must be increased to at least 4500 calories per day. The specific therapeutic agent must be administered in amounts three times as large as those used for the mild case. Absolute rest in bed is imperative. Parenteral liver extract (probably the crude preparation is more efficacious than the refined) given intramuscularly in doses of 20 ml three to five times daily in addition to the wheat germ yeast or liver extract by mouth is often beneficial, especially to patients with persistent vomiting or diarrhea. Niacin orally (50 mg ten times daily) or niacinamide parenterally (50 mg in physiological solution of

sodium chloride two or three times daily) is astoundingly effective. Healing of the oral and dermal lesions even in the most severe cases usually begins within seventy-two hours after treatment is begun, and the relief of the psychoses of pellagra is spectacular.

**Special Treatment of Symptoms** Symptomatic treatment often aids in remitting the disease. Exacerbation of the stomatitis, vomiting, diarrhea and abdominal pain must not deter the physician from continuing the administration of proper diets, specific therapeutic agents and indicated symptomatic therapy.

**ORAL LESIONS** The use of a mouth wash is beneficial. The teeth should be brushed gently to avoid severe hemorrhages.

**SKIN LESIONS** Potassium permanganate solution (1:5000) used as soaks offers some relief and in the moist type of lesion diminishes the possibility of secondary infection.

**DIARRHEA** Tincture of opium 2 ml can be given every four hours unless symptoms of overdosage appear. This is sometimes beneficial and is particularly indicated whenever an analgesic is required. The severe case should receive fluids by a parenteral route. The administration of niacin is effective.

**VOMITING** Absolute rest in bed and feed

FIG 61 Photograph showing symmetrical dry scaly pellagrous dermatitis on the feet of a Negro. Note the sharply demarcated borders and the hyperpigmentation at the periphery of the lesions.

ings of an iced fluid such as eggnog, ginger ale or malted milk in small quantities (10 to 15 ml) at intervals of 10 to 15 minutes are necessary and should be continued until the patient has not vomited for 12 hours. Yeast, wheat germ or liver extract should be added to these feedings in amounts of 4 to 5 gm until the daily requirement has been given. In the more severe case, parental liver extract must be given immediately and continued until the patient is able to retain the required amount of the recommended diet together with any one of the potent specific therapeutic materials.

**MENTAL SYMPTOMS** Large doses of niacin or niacinamide result in spectacular relief of the mental symptoms, and their use is indicated instead of sedatives.

**PERIPHERAL NEURITIS** Ice bags and local medications containing phenol (1 per cent) and menthol afford temporary relief. Physical therapy and splints are often beneficial. For use of vitamin B<sub>1</sub>, see Beriberi.

**Prevention** In order to eradicate pellagra persons with organic disease, those who are poor, chronic alcohol addicts, food faddists, and those with improper dietary habits must receive special attention.

**Organic Disease** Organic disease often predisposes to pellagra by affecting the general nutrition and probably by increasing susceptibility. Particular attention to the diet while the disease is being treated prevents the development of pellagra. The incidence of pellagra is abnormally high among people having metabolic diseases, chronic infections, and diseases of the gastrointestinal tract.

**Poverty** Although pellagra often develops as the result of financial inability to buy proper food, lack of knowledge in regard to diet is an important contributing factor. If sufficient amounts of a well-balanced diet are eaten regularly, pellagra will not develop. Education of the poor in correct dietary habits is indicated so that those who can but do not may buy the inexpensive protective foods and those who cannot afford them may obtain protective substances such as yeast and wheat germ through relief agencies.

**Chronic Alcoholism** Chronic alcohol addicts who do not eat adequate amounts of a well-balanced diet acquire pellagra. Alcohol alone does not cause the disease, but it often decreases the patient's appetite and diminishes his food intake. This is easily understood when we consider that often the heavy drinker receives from 3000 to 4000 calories per day from the alcohol alone. When alcoholic pellagrins are induced to

stop drinking, their appetites return, they eat more food, and the disease is arrested and is not likely to recur. Likewise, alcoholic pellagrins who can be persuaded to eat large amounts of food do not have recurrences.

**Improper Dietary Habits** It is a popular fallacy to believe that our customary diets are adequate. Many people live on a diet of narrow range, too high in fats and carbohydrates because of custom, preconceived ideas as to what foods are good for one, and dependence upon the appetite as the guide in the proper selection of foods. Education of the masses in the essential dietary requirements is imperative.

The pellagra develops; this disease because for one reason or another he does not get in his tissues sufficient niacin or materials which act similarly. Large amounts of tryptophan can be converted into niacin. Corn and corn products tend to be low in both salts of niacin and the amino acid tryptophan, hence the association between the endemic pellagra who eats a great deal of maize and maize products and his disease. For over nine years the author has not seen a case of endemic pellagra in the southern part of the United States. The disappearance of this disease, which was so debilitating and rampant a few years ago, has been due to the enrichment program to better dietary habits and to general interest on the part of the medical profession.

## RIBOFLAVIN DEFICIENCY

The importance of riboflavin in human nutrition was observed independently by Seabell and Butler and Vilter. Vilter and Spies. Riboflavin deficiency occurs in either sex at any age and is common in persons

who subsist over a considerable period of time on a grossly inadequate diet. It tends to occur in the spring and to disappear during the summer months. It is probably the most common clinically recognized deficiency disease in the United States.

Diagnosis depends upon the recognition of characteristic angular stomatitis associated with transverse fissures in the corners of the mouth. Another lesion occurring less frequently is the accumulation of greasy seborrheic material around the alae nasae and occasionally around the eyes and on the ears. In the Nutrition Clinic of the Hillman Hospital, Birmingham, Alabama, we have observed over 5000 persons with riboflavin deficiency. The symptoms characteristic of riboflavin deficiency are angular stomatitis associated with transverse fissures in the corners of the mouth and lips and an abnormal shiny redness of the mucous membranes of the lips, a shark-skin appearance of the skin around the alae nasae and eyes and occasionally over the ears and malar prominences, ocular symptoms characterized by bulbar conjunctivitis, lacrimation, burning of the eyes and failing vision and invasion of vessels of the cornea (Figs 55-56). An infrequent but spectacular lesion associated with deficiency of riboflavin in the tissues is termed the "magenta tongue." It is characterized by flattening and mushrooming of the papillae, giving the tongue a granular or pebbly appearance and a purplish red discoloration which has been attributed to dilatation and proliferation of the capillaries with slowing of the circulation. These symptoms disappear within four to six days after the administration of adequate amounts of riboflavin.

**Treatment.** In the average case the administration of 5 mg of synthetic riboflavin three times a day was followed by the disappearance of the lesions within three to six days. Two patients who were given 2 mg of synthetic phosphoric acid ester of riboflavin three times a day showed similar improvement within six to eight days. In these cases Ashe and Spies found that the daily excretion of flavin (determined as riboflavin) was 18 per cent below normal. Diminished output of flavin has been observed in other patients who have not had the typical lesions described. After the administration of riboflavin the level in the urine rises. These studies suggest that in persons subsisting on inadequate diets riboflavin deficiency is not uncommon. Our figures indicate that the riboflavin require-

ment for an adult is approximately 3.5 mg daily.

## ACRODYNIA

(Pink Disease)

**Definition.** Acrodynia or pink disease is primarily a disease of infancy and early childhood characterized by painful red swollen hands and feet, tachycardia, hypertension, hypomotility, mental apathy, anorexia and photophobia. The onset is insidious and the disease may persist for months. The outcome is favorable unless terminated by intercurrent infection.

**Etiology and Morbid Anatomy.** The disease is of unknown etiology. It is impossible to trace familial incidence. It usually occurs between the ages of four months and three years. Transmission of the disease to other members of the family rarely occurs. One theory is that it is the result of a dietary deficiency, but it does not appear to be a deficiency of any of the known vitamins. Another theory is that it is caused by a filterable virus, but no virus has been isolated. Histological studies show a degenerative process which affects both the central and peripheral nervous systems. There is widespread peripheral nerve degeneration with demyelination of the nerve sheaths. The anterior horn cells and the cells of the posterior root ganglia often show chromatolysis. It is possible that acrodynia includes a number of disease entities.

**Symptoms.** Because of the insidious onset the mother frequently cannot state (with any degree of accuracy) when the disease began. In some instances the onset is associated with an upper respiratory infection or is manifested by cessation of growth and progressive loss of weight followed by fretfulness, sleeplessness and refusal of food. The child is excessively irritable and usually lies curled up in a knee-elbow position with his face buried in

a pillow. He constantly rubs together his reddened desquamating hands and when exposed to light he rubs his eyes. He cries frequently especially when disturbed. The cheeks are bluish red and in many cases the tip of the nose is red. Areas of hyperemia alternating with ischemia appear on the skin of the hands and feet. Papular rashes may appear over the whole body.

**Diagnosis.** The diagnosis is based on the presence of painful red hands and feet, peeling of the skin, prostration, perspiration and photophobia accompanied by tachycardia and hypertension. The most constant features of the disease are photophobia, hypotonia and cutaneous rash. The mild or borderline cases are not so clearly defined and in such instances diagnosis is more difficult. The erythema in acrodynia, however, is readily distinguished from that of pellagra or the erythema caused by heat or cold.

**Prognosis.** Generally speaking the mortality rate is low. When death occurs it is usually the result of an intercurrent infection.

**Treatment.** Ignorance of the true nature of the disease prohibits specific therapy. In our Nutrition Clinic where several of these patients are treated each year we use two principles. First we attempt the judicious use of barbiturates or other sedatives and we do everything possible to ensure the ingestion of a high vitamin high-caloric diet. Secondly we give a mixed vitamin preparation containing 50 mg of niacinamide, 5 mg of thiamine, 1 mg of riboflavin and 50 mg of ascorbic acid in the baby's milk three times a day. At times we have given parenteral liver extract. The mixed vitamin preparation and liver extract both seem to give considerable symptomatic relief. It has recently been reported that infusions of saline and the administration of desoxycorticosterone acetate in debilitated infants with pink disease afford prompt improvement. This is based on the presumed presence of adrenal insufficiency.

#### BURNING FEET SYNDROME

This disabling disease of nutritional origin was little known to American physicians

prior to World War II. It has been described under various names but has been noted in the Orient among underfed people for more than one hundred years. Painful burning feet were so common among the prisoners of war in the Orient that sleep was practically impossible and walking difficult. The patients improved slowly with general dietary improvement. At best malnutrition and undernutrition are associated with this syndrome because it appears only among groups on very restricted diets. The incidence of endemic nutritive failure among the population of the southeastern United States where the author has worked so long has decreased greatly in the past twenty years. When the incidence was high burning feet was a common presenting symptom of the patients. Many but not all of them could be relieved by the administration of thiamine. In recent years the general nutrition of the population has improved and the physician rarely sees persons who complain of burning feet arising from general dietary failure. A number of observers have been able to relieve the so-called "burning feet syndrome" by the administration of pantothenic acid.

#### PANTOTHENIC ACID DEFICIENCY

Pantothenic acid is an integral part of coenzyme A and therefore is essential for cellular metabolism. Uncomplicated pantothenic acid deficiency has not been observed in man as this vitamin is present in all food and may be synthesized by intestinal bacteria. Bean and co-workers attempted to induce a pantothenic acid deficiency by the administration of omega-methyl pantothenic acid to human volunteers and by deleting the vitamin from a highly purified diet. The subject given the pantothenic acid antagonist developed easy fatigability, somnolence, paresthesias of the hands and feet, abnormalities of gut, dizziness, postural hypotension, tachycardia, epigastric distress, increased incidence of respiratory infections and changes suggestive of adrenal cortical insufficiency. The symptoms were not relieved completely by the administration of pantothenic acid and could not be reproduced when the diet was low in this vitamin.

Frequently the burning feet syndrome is associated with pantothenic acid deficiency.

### PYRIDOXINE (VITAMIN B<sub>6</sub>) DEFICIENCY

Between 1951 and 1953 many physicians throughout the United States observed that artificially fed young infants taking a pyridoxine (vitamin B<sub>6</sub>) deficient formula developed hyperirritability and convulsive seizures. These clinical observations provided much important information. It was soon recognized that in each case there was a uniform pattern of symptoms varying in degree of severity. The convulsions were unassociated with any other signs of illness and there were no physical findings or laboratory abnormalities indicative of any etiological factor. The infants had normal birth histories and had grown and developed normally until they were at least eighteen weeks of age. The onset of the convulsions was sudden. All the physicians reporting their occurrence found that the infants invariably had been fed on a commercial liquid formula which consisted of defatted cows milk, vegetable and animal fats, vitamins and iron. No cases were encountered in which the infants received the powdered formula which contained pyridoxine. When the infants were fed the powdered formula or when they were given supplementary foods such as cereals, meats, fruits and vegetables or when they were given pyridoxine either orally or by injection the convulsions disappeared and did not recur if a supplement of pyridoxine was continued.

Pyridoxine deficiency in adults has been induced experimentally by Mueller and Vilter through the administration of desoxypyridoxine, a metabolic antagonist of pyridoxine. The clinical manifestations included the development of a seborrheic like dermatitis about the eyes, nose and mouth, a cheilosis which resembled that of riboflavin deficiency and a glossitis which was morphologically similar to that of niacin deficiency. The skin, mucous membrane and lingual lesions remained unchanged when thiamine, riboflavin and nicotinamide were given but disappeared promptly following the administration of pyridoxine.

Although far too little is known regarding the function of pyridoxine in human beings, its essential function had been demonstrated previously. Many years ago an etiological relationship was established between pyridoxine deficiency and convulsive seizures in rats, chicks and pigs. Synthetic pyridoxine was first administered to human beings in 1939 by Spies, Bean and Ashe, who stressed that after the deficiencies of niacin, riboflavin and thiamine were corrected and if the patients remained on

their deficient diets, pyridoxine would produce an additional improvement. Snyderman and associates and Stokes and associates (quoted by Coursin) have made interesting observations on single patients suggesting a relationship between pyridoxine deficiency and convulsive seizures.

### VITAMINS (FOLIC ACID AND VITAMIN B<sub>12</sub>) AND BLOOD REGENERATION

Folic acid, pteroylglutamic acid, appears to be biologically active in the form of 5,6,7,8-tetrahydrofolic acid. In this reduced form it serves as a carrier of a one-carbon unit (C<sub>1</sub>) on the oxidation levels of formaldehyde and formate. The combination of tetrahydrofolic acid and C<sub>1</sub> in the form of the N<sup>10</sup>-formyltetrahydrofolic acid or of the bridged N<sup>10</sup>-methenyl or methylene derivatives, these biologically active forms probably give rise nonenzymatically to N<sup>10</sup>-formyltetrahydrofolic acid, a stable compound known as folinic acid or citrovorum factor. The transfer of a C<sub>1</sub> unit is involved in the following metabolic functions of folic acid: (1) the incorporation of C<sub>1</sub> into the 2 and 8 positions of purines; (2) the formation of the methyl groups of methionine, choline and thymine; (3) the synthesis and catabolism of serine and histidine and the catabolism of tryptophan. Although these activities are probably not the sole functions of folic acid, it is clear that a deficiency of folic acid will have widespread and diverse metabolic effects.

Vitamin B<sub>12</sub>, cyanocobalamin, was first isolated from liver by Rickes, Folkers and their associates in the United States and independently by E. Lester Smith in Great Britain. It consists of (1) a planar porphyrin-like moiety with a cobalt atom in its center; (2) a cyanide bound to the cobalt; (3) 5,6-dimethylbenzimidazole ribotide; and (4) 1-amino-2-propanol. The metabolic functions of vitamin B<sub>12</sub> are not clearly delineated. Claims have been made for its role in the reduction of disulfide linkages to

sulfhydryl groups in thymidine and deoxy riboside synthesis in methyl group formation and in protein synthesis. A conclusive definition of its metabolic functions how ever remains to be accomplished.

Folic acid was the first of many synthetic chemical substances shown to produce blood regeneration in persons with pernicious anemia nutritional macrocytic anemia macrocytic anemia of pregnancy macrocytic anemia of sprue and megaloblastic anemia of infancy. Soon it was demonstrated that folic acid failed to protect against or to prevent the symptoms arising from acute degeneration of the spinal cord so frequently associated with pernicious anemia and it became clear that folic acid was not a complete therapeutic agent for the treatment of pernicious anemia but that it is an essential therapeutic agent for the treatment of the average case of macrocytic anemia of pregnancy and megaloblastic anemia of infancy. It is a useful therapeutic agent in the treatment of sprue and nutritional macrocytic anemia.

Folic acid is an important member of the vitamin B complex. The administration of folic acid or foods which contain it to expectant mothers whose diets are low in folic acid is mandatory. In this way the macrocytic anemia of pregnancy, infancy and early childhood can be prevented. It is recommended that at least 2 mg. per day be administered in the last third of pregnancy if the diet is deficient in folic acid. It is interesting to note that the mother can concentrate folic acid and transmit it through her milk to the infant so as to produce a therapeutic response in the infant with megaloblastic arrest.

During the past eight years by administering folic acid as a supplement to the diet we have enabled numerous patients to continue working. These patients had tropical sprue or nutritional macrocytic anemia were totally incapacitated and probably would have died if specific therapy had not been administered either orally or parenterally. The precise dose of folic acid varies from patient to patient but in the average case 5 to 10 mg. per day and usually much less produces a prompt hemopoietic response which is paralleled by a striking clinical response. The glossitis heals, the patient's appetite increases and his strength rapidly increases.

The bone marrow biopsy and peripheral blood findings in pernicious anemia are indistinguishable from those found in nutritional macrocytic anemia, tropical sprue and nontropical sprue in relapse and the

administration of vitamin B<sub>12</sub> is effective in each of these conditions. A number of types of steatorrhea which sometimes are associated and confused with endemic sprue as a rule are not relieved by this material. It should be emphasized that the average patient who receives vitamin B<sub>12</sub> should receive it parenterally or orally in association with an active intrinsic factor. Parenteral therapy is effective in a higher percentage of cases. When given in small doses by mouth vitamin B<sub>12</sub> does not usually benefit persons with pernicious anemia in relapse unless an intrinsic factor is added.

Pain, tingling numbness and stiffness of the extremities develop when there is a deficiency of vitamin B<sub>12</sub> and this condition may advance to complete or partial paralysis. The symptoms can be ameliorated when treated promptly by injections of vitamin B<sub>12</sub>. The chronic phase of the disease does not respond well to treatment.

## Vitamin C Deficiency

### (Scurvy)

Scurvy is a nutritional disorder caused by prolonged inadequacy of the supply of ascorbic acid. Mild symptoms include apathy, anorexia, fatigability and loss of strength; in more severe cases there is tenderness of the extremities and gums together with a hemorrhagic tendency. The manifestations of the disease depend on the age of the patient. Infantile scurvy

differs from adult scurvy principally in the extent to which the growing bones are involved

**History** The name "scurvy" appeared first in the Middle Ages as a folk word having various forms phonetically allied in several European tongues. The Latinized *scorbutus* is an artificial implant.

Possibly the earliest clear-cut description of the disease was made by de Joinville among Crusaders of the thirteenth century. To Joseph Lind, an officer of the British navy, belongs the credit of amassing convincing evidence first that scurvy is a disorder of nutrition and not a contagion or strictly an occupational disease and second that it results not from excessive consumption of certain articles of diet but from insufficient intake of others. His *Treatise on the Scurvy*, published in 1753, was ultimately responsible for the introduction of lemon juice into the seaman's ration. Even well into the twentieth century scurvy continued to threaten the success of voyages of discovery and to stalk the victims of blockade, siege and shipwreck.

Scurvy was produced in laboratory animals by Holst and Frolich, whose studies were published in 1907.

In 1928 Szent Gyorgyi isolated from the suprarenal glands of oxen and from various plant sources a crystalline compound of formula  $C_6H_8O_6$  which he named hexuronic acid. The wide distribution of this compound in animal tissues and in growing plants was soon appreciated as were also its strong reducing properties but it was not until 1932 that Szent Gyorgyi determined by appropriate feeding experiments that he had been dealing with the specific antiscorbutic factor, vitamin C. Simultaneously and independently King and Waugh isolated a highly active antiscorbutic compound from lemon juice and showed that it was identical with hexuronic acid. By common agreement the latter term was abandoned in favor of *ascorbic acid*.

**Etiology:** Ascorbic acid is essential for the proper formation of collagen by fibroblasts and there is evidence that it participates in the production of intercellular material in other tissues such as the cement substance of vascular endothelium and the attachment of striated muscle cells to tendon. Together with its oxidation product, dehydroascorbic acid, it constitutes within the body an important oxidation-reduction system. Through its function as a hydrogen donor, ascorbic acid serves in converting folic acid to the physiologically active folic acid. In the absence of ascorbic acid the metabolism of aromatic amino acids, especially of tyrosine and phenylalanine, is disturbed. Several additional roles in intermediary metabolism have been suggested but less reliably documented.

Fresh fruits, vegetables and raw meats contain ascorbic acid in sufficient quantity to prevent the appearance of scurvy if the diet is composed largely of uncooked or freshly cooked natural products. The juice of ripe oranges has a fairly constant con-

tent of ascorbic acid at about 0.5 mg per ml. Other citrus fruits, though showing greater variation under market conditions, contain similar quantities. In general, the ascorbic acid content of plant tissues parallels their store of carotenoids or chlorophyll, green leaves and shoots of all kinds as well as tubers, whether edible or those generally regarded as inedible, are sources of vitamin C.

In animal tissues the concentration of ascorbic acid is highest in adrenal hypophysis, corpus luteum, lens and aqueous humor and somewhat less in brain, pancreas, liver, spleen and kidney. It is considerably lower in muscle tissue, distinctly low (about 0.5 to 1.5 mg per 100 ml) in blood plasma and virtually absent from fat. Cow's milk, as processed for urban consumption, does not provide a reliable dietary quota of vitamin C. Chemical synthesis of ascorbic acid from sorbitol is now more economical than is its extraction from natural sources.

The human organism lacks the enzyme system required for the conversion of L-gulonolactone to ascorbic acid, an essential step in the biosynthesis of vitamin C and consequently depends on extraneous sources for its essential requirements. If the supply is cut off for a sufficiently long time, a matter of months, clinical scurvy supervenes. In times of peace and normal economic life the disease is seen as a rule only in recluses and faddists who, from ignorance, boredom or fear of infection, confine their diet essentially to heated, oxidized and therefore ascorbic acid-free foods.

The minimal daily requirement of ascorbic acid has not been accurately determined. A group of British volunteers remained in good health when on a daily intake of as little as 10 mg for nine months and as a result British nutritionists commonly cite 30 mg as the minimal daily intake needed. American authorities on the other hand usually quote a higher figure of the order of 1 mg per kg or for an average adult 75 mg per day. Even on a daily intake of this size there is no assurance that the body's capacity to utilize ascorbic acid has been exceeded or that with additional dietary load retention continues for a time until loss through urinary excretion takes place above a threshold level of approximately 1.5 mg per 100 ml of plasma. On an average diet the normal adult excretes from 5 to 50 mg of ascorbic acid in the urine in twenty-four hours. An increase in the intake augments this output, though

not immediately and not quantitatively. If to an average diet one adds a daily supplement of 500 mg of ascorbic acid, urinary excretion of the vitamin will rise significantly within the first or second 24 hour period and will level off at about 80 per cent of the intake. After this equilibrium has been established, withdrawal of the supplement results in a similarly steep falling off of excretion so that within three or four days the output has returned to the starting level. It would seem in other words that the organism has a limited capacity for storing vitamin C, that on an average diet the stores are not filled to the saturation point and that after saturation, the major portion of the intake is excreted by the kidneys.

Infections and other forms of "stress" rheumatic activity and hyperthyroidism accelerate vitamin C depletion. Withdrawal of ascorbic acid from the diet of a normal subject for a period of one or two weeks causes a clearly detectable change in the economy of the vitamin when a supplement is subsequently added; the daily administration of a liberal quantity of ascorbic acid after such a vitamin free period may fail to produce an increased output in the urine for four days or even longer.

In scurvy the body stores of ascorbic acid are significantly depleted; the plasma concentration is zero or nearly so, and the small quantities reported present in urine may well reflect merely the error of analysis. In the depletion process the white blood cells and platelets which normally contain ascorbic acid at a concentration some thirty times as great as that of cell free plasma retain their stores with relative avidity, yet they likewise lose their ascorbic acid by the time symptoms appear. On administration of the vitamin, relief of symptoms and signs of scurvy precedes the restoration of a normal urinary output of ascorbic acid or the establishment of a stable plasma concentration at a normal level.

The time required to bring out symptoms of scurvy on a deficient diet varies greatly in ordinary clinical circumstances since complete deprivation is seldom encountered except under experimental conditions and since the intake of even a small quantity of the vitamin tends to delay the onset of symptoms. In a notable human experiment carried out by Crandon under controlled conditions of strict dietary deficiency, the subject's plasma level of ascorbic acid fell to zero by the forty first day; the white

blood cells and platelets became depleted after four months yet objective signs of scurvy in the form of cutaneous hemorrhages were not evident until the 161st day of the experimental diet. These intervals presumably represent approximately minimal values. Subjective symptoms of a less specific nature—*languor*, *fatigability* and *anorexia*—preceded the appearance of objective signs.

Most cases of scurvy seen in infancy develop six months or so after the institution of artificial feeding. A few examples have been reported in infants considerably younger but in these instances the mother could invariably be shown to have subsisted on an inadequate diet during pregnancy and since the concentration of ascorbic acid in fetal tissues is directly influenced by the mother's diet, the period of vitamin deprivation as it affected such a mother's infant obviously commenced before birth. The concentration of ascorbic acid in human milk while invariably higher than that in maternal plasma, closely reflects the adequacy of the mother's intake.

**Pathology.** The gross morbid anatomy of scurvy is largely that of the associated hemorrhages. In the skin these may be ecchymotic or petechial. Minute extravasations often dot the hair follicles of exposed or dependent parts while larger ecchymoses are found in regions subjected to trauma. Subcutaneous fascial or intramuscular hemorrhages may occupy sites of particular mechanical stress.

Subperiosteal hemorrhages are relatively uncommon in adult scurvy but invariably accompany severe cases of infantile scurvy owing to loosening of the periosteal attachment which is a primary feature of the functional pathology of the disease. Capillary bleeding may dissect the periosteum free over a large area. Most commonly these subperiosteal hemorrhages are found at the lower end of the femur, the upper end of the humerus, both ends of the tibia and at the costochondral junction of the middle ribs.

In growing bones the histopathology of scurvy is distinctive, revealing a suppression of the orderly growth process and of the normal conversion of cartilage matrix into bone. In addition, hemorrhages may be found in the interior of the bone at the cartilage shaft junction together with fractures of the minute columns of cartilage matrix and at times dislocation, separation or impaction of the epiphysis.

The lesions of the gums will be described

among the clinical signs Scurvy causes striking changes in the teeth separation of the odontoblast layer from the dentin and development of hemorrhages within the pulp cavity Although the teeth are capable of functional recovery the healing process is never anatomically complete so that histological identification of an antecedent attack is possible throughout life

The effects of suppression of collagen formation become evident in experimental studies of wound healing such as those which Crandon added to his self imposed nutritional privations By the time hemorrhagic manifestations of scurvy had appeared a little more than five months after initiation of the C free diet a freshly inflicted surgical incision showed no evidence of organization for some days until the administration of ascorbic acid started the healing process on its normal course

**Symptoms** The symptoms of the disease begin as a rule insidiously with a feeling of general weakness and inadequacy negativism depression or even melancholia The normal degree of alertness is replaced by a disposition to inactivity Appetite fails and the taking of food is additionally hampered by painful gums which are disposed to bleed easily The skin is dry and rough with prominent gritty follicles In areas in which capillary pressure is high as in the lower extremities or in regions distal to constricting bands of clothing minute hemorrhages are to be seen in the hair follicles

Increasing mental depression accompanies progressive loss of muscle power The lips become cyanotic and the gums begin to show erosion of the mucous membrane at their margins with formation of friable clots adherent to the teeth almost invariably these are accompanied by fetid breath The lower extremities develop swellings in the muscle masses particularly in the extensors and adductors of the thighs and in the calves and the knees are held in partial flexion efforts toward full extension are accompanied by pain There is increased swelling of the subcutaneous tissue of the feet particularly between the Achilles tendon and the tibia Tenderness on deep pressure may be elicited in any part of the limb Finally ecchymoses appear especially over the lower third of the thigh above the malleoli or on the dorsa of the feet Hemorrhage into the muscle masses or beneath the periosteum is generally accompanied by induration There may be either microscopic or gross hem

aturia Not all the symptoms mentioned are necessarily of simultaneous occurrence Mental depression is rarely absent but ecchymoses may occur in the absence of stomatitis and the disease may be clinically recognizable before extensive intramuscular or subperiosteal hemorrhages have taken place

With healing recovery occurs in more or less the following order stomatitis mental depression induration cutaneous hemorrhages and last follicular keratosis

In particularly severe cases the course is progressively downhill The teeth loosen and fall out often with uncontrollable hemorrhage There may be hemorrhage from the nose stomach or intestines or an extravasation of blood may suddenly appear without provocation at some bizarre site as in the orbit causing proptosis and ecchymosis of the eyelids The pulse becomes rapid and weak and the patient may suddenly die from relatively mild physical exertion or may expire from progressive prostration or intercurrent infection

In infants apathy and irritability alternate but anorexia is the rule In contrast to the febrile state of older patients elevation of temperature is almost always present Petechial hemorrhages are generally less conspicuous than in the adult The tenderness of the involved extremities and the changes in contour brought about by subperiosteal hemorrhages and epiphyseal infraction are often extreme On the other hand the oral signs are usually limited to swelling and purple discoloration of the gums around deciduous teeth which have already erupted or are about to erupt while the formation of large vegetations is rare and fetor exceptional Anemia of some degree is almost always found The leukocyte pattern is not affected in uncomplicated cases

Scurvy often goes hand in hand with other deficiency diseases

**Diagnosis** The diagnosis of scurvy is generally made on the history of an inadequate diet combined with the detection of some of the more obvious physical manifestations of the disease Bleeding which does not depend on some demonstrable cause must arouse suspicion Tenderness may be confined to the region of the long bones of the lower extremities or may at times be so capricious in its orientation as to bring the patient under suspicion of neurosis or even malingering The changes in the gums produced by scurvy may be simulated in thrombocytopenic purpura leukemia or

mercurial poisoning. In infants the roentgen picture in the long bones is pathognomonic but in children and especially in young adults this diagnostic aid is less helpful. Subperiosteal hemorrhage is not ordinarily recognizable in roentgenograms until some days after the institution of effective therapy and until the formation of new bone has been resumed in the elevated periosteum. Demonstration of capillary fragility is suggestive but must be supported by more specific evidence.

Biochemical assay of the ascorbic acid stores plays a salient part in diagnosis. A plasma level close to zero accompanies all cases of untreated scurvy but identical values may be found in many subjects who are symptom free and who in consequence cannot be described as scorbutic. The same may be said of low urinary concentrations. Accurate evaluation of the degree of depletion may be achieved in any of three ways: (1) simultaneous determination of the concentration of ascorbic acid in the patient's plasma and in the white cell and platelet layer of centrifuged blood; (2) measurement of the plasma level in the fasting state and after intravenous or intramuscular administration of a test load of ascorbic acid; (3) daily estimation of the total urinary excretion of ascorbic acid for several days after liberal dosage of the vitamin (of the order of 500 mg daily). Depleted stores are indicated in (1) by low values in both determinations, in (2) by a low flat 4 hour curve, in (3) by a delay of two days or more in the rise of urinary excretion.

Since the response of a scorbutic patient to specific antiscorbutic therapy is usually prompt and dramatic, a simple therapeutic diagnostic test is rational and often decisive.

**Prognosis.** Scurvy is readily amenable to treatment provided it is recognized in time. Convalescence prolonged more than a month after the institution of adequate antiscorbutic therapy usually reflects the presence of some additional dietary deficiency, e.g. protein, thiamine, riboflavin or niacin. Conspicuous as is the tendency to hemorrhage in the symptomatology of the disease, fatal bleeding is rare.

**Treatment.** In a therapeutic test for diagnostic purposes the daily administration of 250 mg of ascorbic acid may be expected to dispel anorexia, relieve mental depression to a considerable degree, eliminate tenderness of the extremities and obviate the appearance of fresh capillary hemorrhages within two days to a week, provided these

symptoms have their origin in a deficiency of vitamin C. The total quantity of ascorbic acid required to resaturate a scorbutic patient varies from about 2 gm up to ten times that amount. Absorption of orally administered ascorbic acid is usually complete or nearly so, appreciable reduction in absorption occurring only in the presence of diarrhea or chronic disease of the intestinal tract. Solutions of ascorbic acid are well tolerated in the blood stream as much as 6 gm having been given in a single dose without adverse effect. In spite of its acidity a 1 or 2 per cent solution of ascorbic acid in normal saline need not be buffered or neutralized for intravenous injection.

## Vitamin D Deficiency

### (Privational Rickets)

**Definition.** Privational rickets is a disease characterized chiefly by clinical and roentgenologic abnormalities of the skeleton which result from deficient deposition of lime salts in growing cartilage and in newly formed bone. It is a deficiency disease caused by insufficient vitamin D during the age when growth is rapid. Since the human organism is able to supply its need for the vitamin either by ingestion or by autotynthesis in the presence of sunlight, rickets is an expression of the combined absence of two factors, one dietetic and the other environmental.

**Incidence.** The disease primarily affects infants at the age when rapid growth is taking place. Several months must usually elapse before the manifestations are per-

ceptible clinically the disease is therefore extremely rare in the early weeks of life and the majority of cases are diagnosed between the ages of four months and two years. Formerly the incidence was exceedingly high. Observations in different places indicate that from 50 to 98 per cent of the infant population was affected. Today in the United States the widespread use in infant feeding of milks fortified with vitamin D has had an amazing effect in lowering the incidence. In most areas severe rickets is a rare disease. It is observed more commonly in breast fed than in artificially fed infants.

The premature infant is particularly susceptible to rickets. The susceptibility is so extreme that one is almost justified in saying that moderate or severe rickets will develop in all premature infants unless preventive measures are instituted. Twins belong in the same category.

Rickets is predominantly a disorder of the temperate zone. It is rare in the far North where fish constitute the chief source of food; the influence of sunlight prevents its occurrence in the tropics. There is a seasonal incidence in the Northern Hemisphere; the peak occurs during the winter and spring months when the rays of sun from the south are slanting. Environmental variations in the amount of exposure to the sun also account for a greater prevalence in urban than in rural communities. The Negroes and Italians who dwell in the cities of the United States are unusually susceptible to rickets; the susceptibility is accounted for at least in part by the dark pigmentation of the skin which offers a barrier to the penetration of radiant energy.

**Pathology.** Distinctive findings are limited to the skeleton and result chiefly from the failure of deposition of lime salts in growing cartilage and in newly formed bone. The uncalcified bone or osteoid tissue is morphologically similar to normal bone but because it lacks the elements essential for rigidity it is soft and easily distorted. In health the formation of new bone is greatest at the ends of the long bones and at the costochondral junctions; in these places rickets produces the greatest change. Calcification fails in the zone of proliferating cartilage cells which then persist in scattered tongue-like aggregations. Capillaries from the shaft invade the region between cartilage cells and carry with them an envelope of connective tissue. Thus the regular "epiphyseal line" of health

disappears and in its place there develops a zone composed of osteoid and connective tissues, blood vessels and cartilage cells. This is the rachitic metaphysis. It is soft and in response to external stress the bone will bend in this region. The constant pull of muscles and tendons tends to mushroom the firm epiphyseal cartilage into the metaphysis. The resulting increase in circumference is the epiphyseal enlargement of rickets.

Evidence of the disorder is also found in the shafts. In healthy bone the process of destruction by osteoclasts and replacement by osteoblasts is continuous; in rickets the process is similar except that replacement is by osteoid rather than by osseous tissue. Trabeculae of bone come to be enveloped by a mantle of osteoid tissue. Fractures are frequently found. In health the production of cortical bone is a function of the periosteum. In rickets the periosteum is sometimes excessively active in laying down concentric layers of lime deficient bone so that the shaft becomes considerably increased in thickness.

When rickets begins to heal the first change results from calcification of the matrix about the more recently differentiated cartilage cells. The new epiphyseal line which is formed is demonstrable by roentgenogram and demarcates the distal end of the rachitic metaphysis. The hiatus which remains between the new line and the shaft is obliterated more slowly.

**Etiology.** *Metabolic and Chemical Aspects.* Vitamin D has a profound effect both on the absorption of calcium and phosphorus from the intestine and on the reabsorption of phosphorus by the renal tubules. During rickets large amounts of ingested calcium and phosphorus are excreted in the stools. With healing a strongly positive balance is established until the skeleton has been replenished. Thereafter the larger part of the excess phosphorus over that required for growth is excreted in the urine while the bowel continues to be the principal route for eliminating calcium.

The serum of healthy infants normally contains per 100 ml. 10 to 11 mg. of calcium and 4.5 to 5.5 mg. of inorganic phosphorus. According to Howland and Kramer the product of the calcium and phosphorus when both are expressed in milligrams per 100 ml. furnishes an index of the presence or absence of rickets. A product less than 30 indicates the presence of rickets; a product between 30 and 40

may or may not be associated with rickets a product greater than 40 indicates either that rickets is absent or that the disease is undergoing healing. In most cases of rickets the low product results from a deficit in inorganic phosphorus. When tetany complicates rickets the calcium level is affected chiefly.\*

**Symptoms and Physical Signs** The accuracy which the roentgenogram has contributed to the diagnosis of rickets has made it clear that the only characteristic signs are those which pertain to the skeleton. Other manifestations such as irritability, excessive sweating or muscular hypotonia are either difficult to evaluate or common to so many disorders as to be of no aid in recognizing the disease. As a single exception the manifestations of tetany during infancy strongly suggest the presence of rickets. Tetany however is a complex of symptoms which accompanies only a small fraction of all cases of rickets and which may occur from causes other than those responsible for rickets. The skeletal signs of rickets are the combined result of the softened state of bone in the regions where growth is occurring and of the external stresses to which these regions are exposed. Since age is a factor in determining the sites of rapid growth and since new stresses come into play when the child learns to sit and to stand it is apparent that the manifestations of rickets must vary in relation to the age at which they develop. Long after the disease has ceased to be active the residual deformities are evidence of the age at which the process was most intense.

Craniotabes may be the earliest demonstrable sign of rickets. It is rare after the eighth or ninth month of life. It develops in the occipital or parietal bones in one or more areas removed from the lambdoidal suture and invariably on that side of the head upon which the infant has habitually lain. It is usually associated with softening along the suture line. Craniotabes is often overlooked on routine physical examination; its presence is detected by pressure with the finger over the probable sites of involvement and the finding of relatively soft areas where the skull buckles and snaps back when the pressure is released. The sensation is much the same as one

experiences when pressing on a celluloid ping pong ball. As the infant approaches the end of the first year of life craniotabes generally disappears even though the rickets continues to be active. By this time however the skull may present other evidence of the disease. The eminences of the frontal and parietal bones become unusually prominent and later are thickened into actual bosses which produce a square head (*caput quadratum*). Sometimes the eminences stand out as four rounded elevations separated by depressions which mark the lines of sutures (*hot cross bun head caput natiforme*). Rickets also results in delayed closure of the fontanels. In severe cases the anterior fontanel may still be membranous at the age of three or four years.

**Thoracic deformities** belong among the early signs of rickets. Rapid growth of the ribs during infancy renders the costochondral junctions particularly the sixth and seventh unusually susceptible. Here rounded enlargements make their appearance and can be palpated along a line which extends downward and laterally on either side of the chest. This is the *rachitic rosary*. As the disease progresses the weakened metaphyses of the ribs yield to the force of negative pressure in the thorax and bend inward. When the enlargements at the rib-cartilage junctions are palpable externally they are even more prominent on the inner wall of the thorax. Finally an external groove or depression develops along the line of the rosary. At its lower end the groove merges with a girdle-like depression (*Harrison's groove*) which appears when the ribs have bent inward along the attachments of the diaphragm. Harrison's groove is generally accentuated by flaring of the lower ribs and distention of the abdomen. Park and Howland have pointed out that the functional embarrassment which attends severe rickets of the thorax may actually endanger life. The thoracic cage instead of expanding with each downward excursion of the diaphragm may even become more constricted; pulmonary ventilation is further reduced by wide areas of atelectasis; respiration is rapid and difficult and a relatively mild infection may have a fatal termination.

Enlargements at other epiphyses develop more slowly than at the costochondral junctions but are often well developed before the end of the first year of life. They are recognized most easily at the

\*Rickets of etiology other than vitamin D deficiency is discussed elsewhere in the text under the headings of Fanconi's Syndrome, Phosphorus Diabates, Vitamin B Resistant Rickets, Hypophosphatasia, Tubular Acidosis, Cystic Fibrosis, Cystinosis and Renal Rickets.\*

wrists and ankles where the subcutaneous tissue is relatively thin. When the swelling is slight it is difficult to be sure that one is not dealing with the normal protuberances of the malleoli or styloid processes. In examining the wrist the writer has made it a practice to palpate the dorsal as well as the lateral aspects since an abnormal swelling at the former surface is less liable to be confused with normal styloid processes. Another type of bony enlargement may result from excessive production of subperiosteal bone. In the hands it leads to fusiform enlargement of the proximal and middle phalanges (*string of pearls deformity*).

Most conspicuous among the permanent malformations caused by rickets are the *bending deformities*. To a large extent they originate when the disease continues to be active after the child has learned to sit. The rachitic child shows little inclination to engage in the incessant activity which characterizes his healthy peers. A posture once chosen becomes habitual and he sits for hours in essentially the same position. The resulting stress on the skeleton leads to deformity not only because the bones are unusually yielding but also because the direction of application is unusually constant. Commonly the child sits with thighs slightly spread apart and with one lower leg crossed over the other; the hands are placed on the floor or on the thighs to assist the spine in holding the trunk erect. The pull of gravity on the foot is augmented by that of the Achilles tendon so that the lower epiphyses of the tibia and fibula are displaced backward producing an angular deformity (*saber shin*). At the time of its origin the maximal convexity is just above the ankle. With increasing age the bones grow in length beyond this site and ultimately the greatest bend is about one third the way up the shaft of the tibia. Stress on the femur from the same posture leads to lateral and forward bowing; and the femoral head is bent forward toward the shaft (*coxa vara*). That portion of the spine which is unsupported by the thorax is unusually vulnerable and marked lumbar kyphosis is not uncommon. The combined deformities of lumbar kyphosis, pot belly and flattened thorax produce a striking picture when the child is viewed in profile: the outline is that of an erect truncated cone with the base at the level of the navel. Less conspicuous bending deformities may develop in the upper extremities. The

humerus bows outward and the lower epiphyses of the radius and ulna may be bent to one side or the other depending upon the direction in which the hands are habitually turned. When the child with rickets has learned to stand the stresses are altered. Kyphosis is replaced by lumbar lordosis, coxa vara is increased and bow legs or knock knees make their appearance. The significant rachitic flattening of the pelvis probably begins during infancy from the force of gravity and is increased by the stresses applied during sitting and standing.

**Diagnosis by Roentgenogram** The roentgenographic changes characteristic of rickets are most easily recognized in pictures of the lower ends of the radius and ulna. The earliest changes are seen almost exclusively at the cartilage shaft junction. The normally sharp termination of the shaft becomes blurred and finely irregular (*fraying*); the line of termination tends to become concave (*cupping*); the end of the bone is widened (*spreading*); and in some instances *cortical spurs* may be present at the lateral margins where lime salts have been deposited in the perichondrium which is adjacent to the periosteum. As the disease progresses to the moderate and more severe stages the alterations become unmistakable. The spreading increases; the end of the shaft is hollowed out into a crater and the fraying widens into a fringe which may be 1 cm. or more in width. Severe rickets is also attended by distinctive roentgenographic findings in the shaft. These include marked osteoporosis, either thinning or sometimes a lamellated type of thickening of the cortex and cloaking of the shaft with rarefied subperiosteal bone. Change in the shaft however is rarely useful in establishing an early diagnosis and is a less sensitive index of the progress of successful therapy than is the cartilage shaft junction.

The beginning of healing is heralded in roentgenograms by the appearance of new deposits of lime salts in the zone between bone and cartilage. Particularly prominent is the reappearance of an epiphyseal line at the proximal boundary of the cartilage. At this stage the end of the bone is marked by two horizontal lines between which the area of greatest disorder is isolated. The final obliteration of signs of the disease in roentgenograms may require many months.

**Prophylaxis and Treatment** The Food and Nutrition Board of the National Research Council has recommended that normal infants receive a daily dosage of 400

to 800 international units of vitamin D. Vitamin D milks either fresh or reconstituted from the evaporated state furnish about 400 units per quart. Full term infants reared from birth on formulas made from vitamin D milk do not acquire clinically detectable rickets. mild roentgenologic rickets if it develops disappears as growth continues. Since young infants ingest less than a quart of milk a day and because the deleterious effect of slight vitamin over dosage is unimportant most physicians prescribe a small supplement.

Cod liver oil to be acceptable by the U.S.P. must contain 85 units of vitamin D per gram (400 units per teaspoon) the products of the better pharmaceutical houses are generally more potent. Concentrates contain from 50 to 300 units per drop. The physician should be aware of these variations in prescribing dosage. In infants on formulas made from vitamin D milk do not derive benefit from a supplement of more than one teaspoon per day of cod liver oil of minimum U.S.P. strength for infants on nonenriched formulas two teaspoons are ample. When concentrates are used the dose must be measured in drops.

When active rickets must be treated or when the disease is to be prevented in premature infants one of the many available concentrates should be prescribed. Dosage in the neighborhood of 5000 units daily is satisfactory.

### Vitamin E Deficiency

In 1922 Evans and Bishop first demonstrated the existence of this vitamin. Five years later Evans and Burr wrote a monograph on the subject which is the foundation of our knowledge today.

The term "vitamin E" has been applied

to alpha tocopherol and to a lesser extent to the other tocopherols and certain synthetic substances which restore fertility to the vitamin E depleted rat. Vitamin E is synthesized in plants. The vegetable seed oils such as wheat germ oil and cotton seed oil contain tocopherols. In 1936 Evans, Emerson and Emerson isolated three tocopherols: alpha, beta and gamma.

Experimental studies on animals carried out under standardized conditions have produced distinct results. Symptoms of vitamin E deficiency appear earlier in the male than in the female rat. The weight of the testes decreases and spermatozoa become nonmotile. In the female the fetuses die young if the deficiency is mild; if it is greatly advanced absolute sterility occurs. In rats and rabbits on a vitamin E deficient diet one of the earlier signs is a dystrophy of the striated muscles and greatly increased urinary creatine. After the administration of vitamin E the creatine content of the urine decreases promptly. No such definite changes have been found in the urine of man with any neuromuscular disturbance. Vitamin E has a remarkable influence on the storage of vitamin A in experimental animals. It is widely employed as an antioxidant.

Experimental studies on human beings have not yet demonstrated sufficient usefulness of vitamin E to warrant making definite claims as to its role in human nutrition. It is claimed that it has a beneficial effect in habitual abortion and it has been reported to be beneficial in primary fibrosis. These claims have not been substantiated, however. Harris, Hickman, Jensen and Spies have shown that the plasma level of tocopherols is lower in persons with nutritional deficiency diseases than in well nourished persons. That the administration of vitamin E produces no harmful effects has been observed by the writer who administered 100 mg. daily to patients for three months without untoward symptoms.

Much work on the action of vitamin E has been carried out but its fundamental action in the human body remains obscure. We know practically nothing of either man's requirement for it or its biological action in human beings. Many of the studies reported have been poorly controlled and their evaluation has been uncritical.

## Vitamin K Deficiency

**Definition** Deficiency of vitamin K is characterized by a hemorrhagic diathesis caused by a lowered blood prothrombin level which is detectable as an increase in the prothrombin clotting time. The disease occurs primarily in patients with jaundice or certain intestinal disorders and in the newborn infant. It is not a true primary dietary deficiency disease but rather a nutritional deficiency in the sense that more factors than vitamin K deficiency alone are necessary for its production. In the absence of complicating factors however vitamin K therapy results in the relief of all signs of the disease.

**History** Dam and his associates in Copenhagen produced a disease in chicks by feeding them a diet washed in ether and observed that a widely distributed antihemorrhagic substance was curative. Dam proposed a term vitamin K for this. Quick in America then suggested that a deficiency of vitamin K was present in patients who had obstructive jaundice. Butt and his associates showed that such patients had a deficiency of prothrombin. Maccorquodale, McKee, Doisy, Almqvist, Klose, Fieser and many other investigators made possible the final isolation and synthesis of vitamin K.

A number of compounds have been tested for vitamin K activity and many have been found active. The two most important at the present time are vitamin K<sub>1</sub> and vitamin K<sub>2</sub>. These are fat soluble and at low temperatures form yellow crystals.

**Etiology** Because of its relationship to prothrombin, vitamin K appears to be necessary for normal physiological function of the liver and for blood coagulation.

In man an inadequate intake of vitamin K is seldom if ever responsible for prothrombin deficiency. The vitamin is widely distributed in chlorophyll-containing plants such as green leaves, alfalfa, spinach and cabbage. As it is fat soluble it is not absorbed from the upper intestine unless conditions are favorable for the absorption of fat. An intact hepatic parenchyma is essential if vitamin K is to enter into prothrombin formation. The vitamin is said to be stored in only small amounts in the body.

Many chronically debilitated persons have moderate hypoprothrombinemia which apparently is not directly attributable to primary vitamin K deficiency.

**Diagnosis** Blood coagulation time and bleeding time have been found unsatisfactory indices of the potential danger of hemorrhage because abnormal values do not appear until hemorrhage is imminent. The measurement of the prothrombin concentration or prothrombin clotting time is a more accurate measure of the tendency to bleed.

The decrease in concentration of prothrombin is a phenomenon in which numerous factors are involved. Bleeding because of prothrombin deficiency may be anticipated in any disease state which results in inadequate intestinal absorption or hepatic utilization of vitamin K. Hemorrhage may result when bile is excluded from the gastrointestinal tract by obstruction due to pancreatic neoplasm, postoperative structure of the common duct, intermittent obstruction by stones or hepatic injury from chronic cholecystic disease or hepatotoxins. The bleeding may manifest itself as a slow oozing of blood from the gums, nose or gastrointestinal tract or more frequently from the incisional site. The hemorrhage occurs most frequently on the first to fourth postoperative days but may occur later. Severe melena or hematemesis may occur though uncommonly and may even be uncontrollable with repeated transfusions. Invariably a prolonged prothrombin clotting time will be found. A multiplicity of factors may produce this situation: loss of blood, trauma, anesthesia, an already depleted prothrombin and excessive administration of Dicumarol or its derivatives which act as a vitamin K antagonist.

Hemorrhage in patients with various intestinal disorders such as sprue, celiac disease, chronic ulcerative colitis, intestinal obstruction with intubation, external biliary fistulas, ileac stomas with profuse discharge, short-circuiting operations and ileitis should lead the physician to suspect prothrombin deficiency. In such conditions it is of utmost importance to follow the prothrombin level. A special problem is encountered in infants who manifest a deficiency of prothrombin at birth. This is attributed to the absence from the intestinal tract of bacterial flora which have some relationship to the synthesis of vitamin K, to the limited absorption of fat to the insufficiency of bile and to the usually

hypermotile gut during the first few days of life. The deficiency of prothrombin in infants is often spontaneously remedied within three or four days after birth. If a surgical procedure is contemplated in the newborn infant, one should follow the prothrombin level with particular caution.

**Treatment.** In most instances vitamin K<sub>1</sub> or K or related compounds are effective in the prevention and control of bleeding due to a lowered prothrombin level. The tendency of a patient to bleed is not always accurately indicated by the prothrombin measurement. Thus when prothrombin deficiency is suspected, therapy should be instituted before bleeding starts. The water-soluble preparations (menadione bisulfite) may be given parenterally when intestinal absorption is poor, but adequate functioning liver parenchyma is necessary in any circumstance.

Minimal requirements for the infant, child, mother, or adult are not known, but a dose of 1 to 2 mg. per day of menadione usually corrects the deficiency unless there is inadequate absorption or an increased need because of diarrhea or sprue. The development of untoward reactions from the oral or parenteral administration of preparations of vitamin K need not be feared. Amounts far above the therapeutic dose have been given to adults (50 mg. orally, 10 mg. intravenously) without the appearance of any signs of toxicity. The oral administration of larger amounts (180 mg. of menadione) to human beings has been followed by vomiting and porphyria.

Bleeding may occur with little warning. It is the writer's practice to determine the prothrombin clotting time of every patient with jaundice or other conditions which may lead to hypoprothrombinemia and to administer vitamin K (2 mg. of menadione) with bile salts orally or water-soluble synthetic progenitors (menadione bisulfite, 4 mg.) parenterally if the prothrombin clotting time is prolonged. One to 2 mg. of a synthetic compound with vitamin K activity together with 1 to 3 gm. of bile salts given orally usually suffices. This dosage should be repeated as indicated.

Preoperative and postoperative care in the jaundiced patient is of utmost importance. After an operation the prothrombin clotting time usually increases to some extent for three or four days but may increase rapidly days later. In such patients the prothrombin concentration should be determined daily for at least four days and then every other day for another ten days.

Some think it is best to administer vitamin K regardless of the postoperative prothrombin clotting time.

The problem of treating patients who are actively bleeding is difficult. The alimentary tract is often filled with blood and the patient frequently is dehydrated and in shock. Such cases usually require transfusion of blood which provides a temporary store of prothrombin for about 8 hours. In cases in which severe bleeding into the alimentary tract is associated with low prothrombin, 25 mg. of a water-soluble vitamin K (menadione bisulfite) can be given either orally or parenterally. Absorption is more certain when the parenteral route is used.

In cases of severe hepatic damage 1 to 2 mg. of substances with vitamin K activity should be administered daily, even though the prothrombin clotting time response is slight. Death from hemorrhagic diathesis rarely occurs when such therapy is applied. Should the usual dose be tripled without effect, no additional amount will be effective. When hepatic damage is severe, utilization of vitamin K substances may prove inadequate.

The newborn infant may be treated by giving 15 mg. of menadione at birth, which prevents transitory hypoprothrombinemia and hemorrhagic disease. Many obstetricians advocate giving vitamin K to the mother 12 to 24 hours before parturition, since it has been found that the infant has a higher prothrombin level when the mother has received vitamin K prior to delivery. The author prefers to give a pregnant woman 2 mg. daily for one week preceding delivery and during labor if necessary.

## Mixed Deficiency Diseases

Diets that fail to supply one nutrient in adequate amounts are deficient in others and every method of study has indicated the predominance of mixed rather than single deficiencies. Accordingly, a person may have a number of diseases simultane-

ously although diagnostic evidence of only one may be apparent at the time he is examined by the physician. The basis of treatment of all patients with deficiency diseases is a diet that supplies liberal amounts of all the essential nutrients. In many instances, however, food cannot be consumed in sufficiently large amounts to supply the patient with the quantities of nutrients needed to restore him to health. Too often it is forgotten that we must treat the patient rather than his disease and that treatment must be adapted to the individual case.

In treating the clinical syndromes of beriberi, pellagra, riboflavin deficiency and scurvy, we give a basic formula consisting of 10 mg of thiamine, 50 mg of niacin, 5 mg of riboflavin, 75 mg of ascorbic acid and 5 mg of folic acid. When we find that the symptoms of one deficiency disease predominate, we add to this formula more of the vitamin specific for the predominating deficiency. In beriberi, 10 mg of thiamine is added daily; in riboflavin deficiency, 5 mg of riboflavin twice daily; in scurvy, 100 mg of ascorbic acid three times a day; and in mild pellagra, 50 mg of niacinamide three times a day. If the pellagra is severe, the patient is given 150 mg of niacinamide three times a day in addition to the basic formula. When the patient is moribund, it may be necessary to resort to parenteral injections in order to prolong and indeed even to save life. When large amounts of glucose are injected daily, we recommend the inclusion of 20 mg of niacinamide, 75 mg of riboflavin and 5 mg of thiamine. In a few instances, we have found it desirable to inject 50 mg of ascorbic acid in physiological solution of sodium chloride.

When there is any tendency to bone marrow failure in patients with definite deficiency disease states, we proceed to make a precise diagnosis. On many occasions it is found that the patients have evidence of nutritional macrocytic anemia or iron deficiency anemia.

Deficiency diseases frequently occur in patients with true pernicious anemia or in women who are pregnant; thus a group of diseases may be operating simultaneously in the patient who may have physiological stress such as pregnancy or lactation or who may have organic and primary disturbances such as failure of the intrinsic factor of the stomach.

The four principles used in treating mixed deficiency diseases are

1. **DIET** 4000 calories, 120 to 150 gm protein, rich in vitamins and minerals.

2. **BASIC THERAPY** Thiamine, riboflavin, niacinamide, ascorbic acid orally.

3. **ADDITIONAL MEDICATION** Synthetic vitamins as indicated orally or parenterally.

4. **NATURAL B COMPLEX** Brewers yeast or extract or rice bran extract and/or liver extract orally or parenterally.

One of the basic formulas employed is

	Daily
Folic acid	5 mg
Thiamine	10 mg
Niacinamide	150 mg
Riboflavin	10 mg
Ascorbic acid	150 mg
Vitamin B <sub>12</sub> and Activator *	10 mcg vitamin B <sub>12</sub>

\* Equivalent to 10 micrograms of vitamin B<sub>12</sub> and intrinsic factor adequate to form its conjugate.

### Sprue and Allied Malabsorption Syndromes

(Tropical Sprue, Nontropical Sprue, Idiopathic Steatorrhea)

**Definition.** Sprue is a chronic disease of unknown etiology without specific gross anatomicopathological changes in which absorption from and motility of the small intestine are impaired. The outstanding clinical features of the disease are the signs and symptoms of abnormal intestinal function and manifestations of associated nutritional deficiency states. Primary (or idiopathic) sprue is to be distinguished from sprue syndromes secondary to diseases with specific pathological lesions which impair function of the small bowel, such as regional enteritis, Whipple's disease, tumors of the small intestine, resections or anastomoses.

Although long considered to be a disease limited to tropical and subtropical climates

sprue has been recognized among patients in the temperate zones of Europe and North America with increasing frequency during the past half century. Many students of the disease agree that tropical and non-tropical sprue (idiopathic steatorrhea) in adults and celiac disease in infants and children are manifestations of the same underlying disease state.

**History** The term sprue apparently derives from the Dutch word *Sprouw* meaning aphthous stomatitis which was first used by Katelaer in 1669 to designate an illness characterized by sore mouth and voluminous stools. The first description of sprue in 1766 is credited to an Englishman William Hillary in the Barbados but it was not until 1880 that the publications of Sir Patrick Manson in China and Van der Burg in Batavia clearly identified sprue and awakened widespread scientific interest in the disease. The extensive studies of Thaysen in 1932 led to more frequent recognition of sprue in temperate climates and pointed to the underlying identity of tropical sprue, nontropical sprue and celiac disease.

**Etiological Factors** The cause of sprue remains unknown. Among many theories the concept that the disease is caused by nutritional deficiency has probably received the widest support. Although severe deficiency states often exist in patients with sprue it has not been possible to prove that they constitute the underlying cause of the disease since they may well be secondary to pre-existing impairment of absorption from the small bowel from other causes. Evidences favoring sprue as a primary deficiency state are: (1) the frequency with which an inadequate dietary intake, particularly of proteins, precedes the onset of symptoms of sprue in tropical climates; (2) the favorable response to treatment with diets adequate in proteins, calories, minerals and vitamins; (3) the favorable response of many patients to treatment with liver extract, vitamin B<sub>1</sub> or folic acid. Evidences which indicate that sprue is not caused primarily by nutritional deficiencies are the fact that the disease develops among many patients either in tropical or temperate climates who have always eaten a very adequate diet and the fact that correction of deficiencies in patients with sprue does not restore intestinal function to normal. Although clinical and hematological responses of such patients to treatment may be satisfactory, careful study during remissions usually reveals evidence of impaired intestinal function and clinical relapses are not uncommon in spite of adequate treatment.

The idea that infection is a primary cause of sprue has been largely abandoned because of the failure to identify an infecting organism and the absence of fever, leukocytosis or anatomicopathological evidence of inflammation in most cases. The fact that some patients seem to respond favorably to treatment with sulfonamides and antibiotics suggests that infection may play a contributory role. Allergy to wheat and rye gluteins has been implicated as an etiological factor in celiac disease and in some cases of nontropical sprue. It is possible that sensitivity to other food proteins may be of importance. As yet the role of allergy as an etiological factor of sprue is incompletely understood.

Constitutional and inherited factors probably are important. The occurrence of the disease in more than one member of the same family is not uncommon and apparently also a racial predisposition exists—light skinned people reportedly being more susceptible than dark skinned people. It is possible that patients with sprue inherit a functional defect of the gastrointestinal tract which may not become evident until precipitating factors such as infection, dietary deficiency, pregnancy, allergy or other unknown influences bring it to light. In order to produce the clinical symptoms of sprue, such extrinsic factors would necessarily be of greater severity and importance in patients with mild constitutional defects than in those with severe defects. This hypothesis might explain the high incidence of sprue in the tropics where dietary deficiency and infection are relatively common. Also it might explain the better response to treatment of most patients with tropical sprue as compared with those with the nontropical variety since in tropical sprue reversible extrinsic factors would more often and to a greater degree be responsible for the production of clinical symptoms.

**Incidence and Epidemiology** Sprue is endemic in certain countries of the Far East including India, Ceylon, Indo-China, the Malayan archipelago, the East Indies, the Philippine Islands, China, Korea and Formosa. It occurs in the West Indies but apparently is rarely observed in Africa. The greatest reported incidence of sprue is among Europeans who have resided in the tropics for long periods. However, this may be due to the fact that the disease often is not recognized in native populations. Although the disease is less common in temperate climates than in many areas of the

tropics it cannot be considered a rarity in Northern Europe and North America where sizable groups of patients with sprue have been observed in a number of medical centers

The incidence of sprue in Puerto Rico apparently is declining though Suarez reported that more than 500 cases have been encountered there during the past thirty years. In India during World War II sprue occurred in epidemic form and became an important cause of morbidity among English and Indian troops and Italian prisoners of war. The epidemics occurred in a seasonal manner but the season varied with different geographical areas and the outbreaks could not be satisfactorily explained on the basis of any single etiological factor. However dietary deficiencies were considered to be of importance particularly among Italian prisoners and Indian troops.

The sex incidence of the disease has varied in different published series. Reports concerning the incidence of sprue among British residents in tropical climates have reflected a preponderance of males. On the other hand females have outnumbered males in series reported from Puerto Rico and New York City while British reports concerning nontropical sprue have indicated that the incidence of the disease is approximately equal in the two sexes.

Sprue may begin at any time of life though the onset of symptoms is most likely to occur between the ages of twenty five and fifty five years. In the tropics the disease rarely begins before the age of ten or after the age of seventy. In many patients with nontropical sprue the onset can be traced back to the occurrence of celiac disease in childhood.

**Morbid Anatomy.** Necropsy has shown depleted stores of fat and atrophy of the tongue and internal organs but has not disclosed lesions in the intestines or elsewhere considered to be specific for sprue. Shortening and blunting of the villi in the small intestine (not attributable to post mortem changes) were noted in some cases. Recently more significance has been attached to the microscopic findings in mucosal biopsies of the small intestine removed at operation or by means of an intestinal intubation technique. Such studies have revealed mucosal atrophy and blunting, flattening and reduction in size of the villi with consequent reduction in the total absorbing surface of the small intestine.

**Pathological Physiology and Chemistry.** All of the clinical and metabolic disturbances encountered in patients with sprue can reasonably be attributed to the impaired intestinal function invariably present in this disease. The fact that identical syndromes are produced by extensive resections of the small intestine and diseases that interfere with its function (anastomoses, tumors, inflammation) is strong evidence in favor of such an explanation. Nevertheless the possibility remains that some manifestations of sprue are due to other primary metabolic abnormalities as yet unidentified.

Studies of patients with nontropical sprue have shown impaired absorption of all nutrients including fat, protein, carbohydrates, vitamins, minerals and even water. Although steatorrhea is the most easily recognized and characteristic feature of this disease, the fecal content of nutrients other than fat also is increased. Such abnormal fecal losses usually associated with diarrhea and often with inadequate dietary intake result in loss of weight and the development of hypoproteinemia, anemia, osteomalacia and hypokalemia as well as other evidences of deficiency states including those of minerals and all the water-soluble and fat-soluble vitamins. Fecal losses of fat may be many times the normal value and the quantity of fecal nitrogen may also be considerably increased. The anemia of sprue can be attributed to the deficiency of essential hematopoietic substances (vitamin B<sub>12</sub>, folic acid, iron and protein), malabsorption of which has been demonstrated in this disease. Multiple deficiencies of these substances may account for the not infrequent failure of any one of them administered therapeutically to correct the anemia completely. Vitamin B deficiency is indicated by glossitis, stomatitis, cheilosis and rarely by the appearance of peripheral neuritis. Other deficiencies of considerable clinical importance are those of vitamin D and calcium which may produce osteomalacia and tetany of vitamin K with its associated hemorrhagic tendency and of potassium which can produce weakness, apathy, mental disturbances and even coma and death in this disease. Tests for the absorption of glucose, vitamin A and carotene have some use in the diagnosis of sprue and other malabsorption diseases.

Röntgenologic studies of the small bowel disclose the so-called deficiency pattern with hypomotility and alterations in

mucosal relief especially of the jejunum. The small bowel is dilated, the mucosal markings are thickened, the contour of the lumen is smooth, the usual markings of the valvulae conniventes are obliterated, barium is clumped in elongated masses and after the bulk of the opaque meal has passed remnants of the barium adhere to the walls giving them a peculiar flecked appearance. There is evidence of hypersecretion or retention of fluid in the small bowel. These changes become less marked during remissions of the disease but seldom disappear entirely.

**Symptoms and Findings.** Diarrhea, weakness and loss of weight are prominent symptoms in sprue. The onset of the disease may be insidious with episodes of loose stools and asthenia which may recur at irregular intervals for many years without becoming sufficiently bothersome to cause the patient to seek medical advice. In other instances the onset may be more abrupt and even explosive in nature. Diarrhea often occurs in attacks lasting a few days to several weeks or longer and as the disease progresses this symptom may become continuous. During diarrheal episodes stools are characteristically nonbloody, soft, bulky, frothy, greasy and light colored but often they may be watery and without gross evidence of steatorrhea even when excessive fat is present. The number of stools varies but it is seldom greater than fifteen in one day. Nocturnal movement of the bowels is common and incontinence of feces may occur. Between spells of diarrhea the stools may appear normal in color and consistency. In rare instances diarrhea may be absent and the patient may even complain of constipation.

Anorexia, weakness and loss of weight may be severe. Loss of 25 pounds or more is common and in extreme cases the patient may lose a third to a half of his customary body weight. A few patients complain of failure to gain weight in spite of an excessive appetite and a large intake of food. Glossitis and stomatitis are frequent symptoms and may cause sufficient pain to interfere with alimentation. Most patients complain of abdominal discomfort, particularly flatulence and distention. However, severe and persistent abdominal pain is uncommon and usually indicates the presence of complications or another disease. Hypocalcemic tetany or skeletal pains associated with osteomalacia are the presenting complaints of a few patients with nontropical sprue but rarely occur in the tropics

where exposure to sunlight apparently prevents the development of vitamin D deficiency.

On physical examination emaciation and dehydration, pallor of the skin and mucous membranes and aphthous stomatitis or glossitis with or without patchy atrophy of the tongue are frequently seen but the most striking feature is the distended protruding tympanitic abdomen. The blood pressure is low and fever is absent except in the presence of intercurrent infection. Edema of the lower extremities is common. In well developed sprue generalized brownish yellow pigmentation suggestive of that seen in Addison's disease may occur or the pigmentation may affect mainly the exposed surfaces of the skin. The liver and spleen usually are not palpable. Although the deep tendon reflexes may occasionally be absent, severe peripheral neuritis and subacute combined degeneration of the spinal cord rarely are encountered. Chvostek's and Trousseau's signs may be positive or manifestations of tetany may be present. Clubbing of the fingers can occur if the disease is of long standing and hemorrhagic tendencies such as petechiae, ecchymosis and bleeding from the orifices are sometimes observed.

Demonstration of the presence of steatorrhea is essential to the diagnosis of sprue. Steatorrhea may be suspected from gross or microscopic inspection of stool but the most reliable method of proving its presence and measuring its degree is by intake-excretion studies. Feces collected over a period of three to six days while the patient is eating a diet containing a moderate amount of fat (70 to 100 gm daily) is analyzed for total quantity of fat. Under the circumstances an excretion of more than 10 gm per day establishes the presence of steatorrhea. Measurements of the percentage of fat in the dry weight of single specimens or of mixed collections of feces may give falsely normal values even though excessive quantities of fat are present if (as frequently happens) the quantity of nonfatty solid constituents of the feces also is increased. Further evidence of malabsorption is obtained when curves showing results of glucose or vitamin A tolerance tests are flat and the concentration of carotene in the serum is below the normal range. An increased prothrombin time resulting from impaired absorption of vitamin K is likewise of diagnostic value. Appropriate chemical analyses of the blood serum or plasma often will give evidence

of one or more deficiency states with low values for proteins, calcium phosphate sodium chloride or potassium. The hemogram and stained smears of the blood may be normal but more frequently they reveal anemia. This is usually macrocytic in type but may be normocytic and hypochromic. Macrocytosis either with or without anemia occurs at some time in the course of almost all cases of sprue though it may not be continuously present. In some patients the peripheral blood picture is indistinguishable from that of pernicious anemia and is associated with megaloblastic bone marrow. The incidence of megaloblastic anemia among reported cases of tropical sprue is considerably higher than that among those with nontropical sprue probably because this type of anemia has frequently been used as a diagnostic criterion for sprue in the tropics whereas in temperate climates more diagnostic emphasis has been placed on the presence of steatorrhea.

Roentgenologic studies of the small intestine may be of considerable diagnostic value in revealing the aforementioned "deficiency pattern" and in ruling out such lesions of the small intestine as enteritis and tumors which can produce a clinical picture closely simulating that of sprue. Although suggestive of sprue the so-called deficiency pattern is by no means pathognomonic of this disease since similar findings have been described in a variety of clinical states. Roentgenographic studies of bone may show evidence of impaired calcification and pseudofractures characteristic of osteomalacia.

**Diagnosis:** The diagnosis of sprue depends on the demonstration of intestinal malabsorption (steatorrhea) and the deficiency states of foodstuffs, minerals and vitamins associated with it. Exclusion of pathologically recognizable entities capable of producing the same syndrome is also necessary. The diagnosis presents few difficulties in well established cases in which a fatty diarrhea, flatulent indigestion, glossitis, anemia, tetany, a protuberant distended abdomen, vitamin deficiencies, loss of weight and muscular wasting are present particularly when symptoms have been present for several years with remissions and exacerbations. However, milder cases without grossly evident steatorrhea or severe anemia are frequently overlooked.

Establishment of the existence of steatorrhea eliminates pernicious anemia, tropical macrocytic anemia, pellagra and other non-steatorrheal diseases which may closely resemble sprue in some respects. The finding

of free gastric acid after histamine stimulation (present in approximately 80 per cent of patients with sprue) and the failure to absorb radiochromium marked vitamin B<sub>12</sub> when intrinsic factor is simultaneously administered also serve to differentiate sprue from pernicious anemia. Pancreatic steatorrhea when due to chronic pancreatitis can almost always be identified by a history of recurrent severe abdominal pain, diabetes or roentgenographic evidence of calcification in the pancreas and when due to carcinoma of the pancreas by the presence of jaundice or a progressive downhill course. Roentgenologic examination of the small intestine helps to rule out regional enteritis and tumors of the small bowel though at times the latter can be recognized only by surgical exploration. Biopsy of the small intestine or mesenteric lymph nodes is necessary to establish an unequivocal diagnosis of Whipple's disease though this may be suspected when the sprue syndrome occurs in a white man with a history of arthritis, fever, abdominal pain and a downhill course.

**Prognosis:** The course of sprue is characterized by remissions and exacerbations which make difficult the evaluation of any particular therapeutic measure. In general however the symptoms tend to progress until treatment is instituted. A large majority of patients respond satisfactorily to treatment particularly those with severe deficiency states. Remissions are often maintained as long as therapeutic measures are continued but relatively few patients are cured in the sense that they can permanently dispense with all therapeutic precautions. Critical study of patients who have made a complete clinical and hematological recovery from either tropical or nontropical sprue usually reveals evidence of impaired function of the small intestine (malabsorption, abnormal motility). Few carefully conducted intake-excretion studies of such patients have been carried out but of those reported most show a return toward normal rather than full attainment of a normal state. Remissions from sprue are often incomplete and relapses may occur even during periods of adequate treatment or sometimes years after an initial episode of the disease.

Many patients under treatment for sprue may live many years in a satisfactory state of health. Others experience periodic recurrences which may become progressively more resistant to therapy while a few may be resistant from the beginning of treatment. Death may be due to a variety of

causes including cachexia infection hem orrhage (hypoprothrombinemia) and potas sium deficiency

**Prevention and Treatment** Since the cause of sprue is unknown there is no completely satisfactory method of prevention Avoid ance of residence in those areas of the tropics where the disease is common and ingestion of a well balanced diet rich in animal protein should be of prophylactic value

In the treatment of the disease complete dependence should not be placed on any single therapeutic measure but rather a program of treatment designed to avoid irritating or overburdening the malfunctioning bowel and to correct the deficiency states should be followed Physical and emotional rest including rest in bed are helpful in establishing remissions Dieto-therapy is of fundamental importance Be cause fat causes abdominal discomfort and diarrhea the amount of it in the diet is restricted to 50 to 70 gm per day The diet is rich in calories vitamins and proteins (particularly those of high biological value) and is composed of foods that leave only a moderate amount of residue A large proportion of the carbohydrates are those from fruits and simple sugars Recently a diet free of wheat and rye gluten first used successfully in the treatment of celiac disease has been found efficacious in the treatment of some patients with non tropical sprue

Liver extract vitamin B<sub>12</sub> and folic acid have all been recommended as specific treatment for sprue and impressive clinical and hematological remissions have resulted from their use particularly in patients with tropical sprue with megaloblastic anemia However maximal benefits from these hematopoietic agents are usually obtained only when dietary treatment is simultaneously administered and the remissions they produce are not always complete They have no demonstrable effect on the steatorrhea of nontropical sprue and have not been shown to correct completely the absorptive defect in the tropical variety The administration of one of them however is always indicated in the presence of macrocytic anemia and perhaps may be of value also in nonanemic patients who do not respond to dietary treatment alone Some patients with macrocytic anemia will respond to one of these agents after being found resistant to another Dosage should be individualized Concentrated liver extract is given intramuscularly in doses of 10 ml each day for three days then 10

ml twice weekly for three months and then a maintenance dose of 10 ml weekly Vitamin B<sub>12</sub> also is administered parenterally according to a similar time schedule in doses of 15 micrograms Folic acid may be administered either orally or parenterally The usual dose is 15 to 20 mg per day for two weeks then 10 or 15 mg daily until complete symptomatic and hematological remission have been attained The maintenance dose is 25 to 50 mg per day Folic acid is contraindicated in patients with neurological involvement

Deficiencies of other vitamins and minerals are corrected as necessary Each patient should receive at least one multiple vitamin capsule daily and if evidence of vitamin deficiencies exists large additional doses of the several vitamins may be given Water soluble preparations having vitamin K activity given orally in doses of 4 mg daily will usually correct a hemorrhagic tendency and return the prothrombin time to normal The vitamin B complex may be given in large doses to patients with peripheral nerve lesions and glossitis Vitamin D in daily doses of 50 000 to 400 000 IU orally may be given in the treatment of osteomalacia and tetany To such patients calcium is administered orally in the form of calcium lactate 1 to 4 drams three times a day depending on the severity of the condition Potassium deficiency is corrected by the oral or parenteral administration of potassium salts Patients with iron-deficiency anemia may require parenteral administration of iron because oral preparations are poorly tolerated and poorly absorbed Blood transfusions are sometimes helpful in controlling intractable anemia and severe hypoproteinemia

Cortisone hydrocortisone prednisone prednisolone and corticotropin are useful as a supplementary treatment in patients who do not respond satisfactorily to the usual measures The object in their use is to establish a remission and then gradually withdraw the medication entirely Thus the patient is spared the dependency on steroids and the troublesome and sometimes dangerous side-effects which result when high level dosages are maintained over long periods as well as the relapses which often occur when such treatment is discontinued The starting daily dose of cortisone is generally 100 mg given orally in four doses of 25 mg each After one to three weeks the time depending on the clinical response the total daily dose is gradually reduced over one to four months and finally discontinued if relapse does not

occur. Repeated courses may be administered for exacerbations of the disease.

# Diseases of Metabolism

## Inborn Errors of Metabolism

### INTRODUCTION

In 1908 A. E. Garrod pointed out that not only gross anatomical malformations but also more subtle metabolic defects may be genetically determined citing as examples albinism, alkaptonuria, cystinuria, and pentosuria. This concept of inborn errors of metabolism has proved to be extraordinarily fruitful. It is now apparent that any segment of the total of metabolic processes—protein, carbohydrate, lipid, nucleic acid, electrolyte, porphyrin or pigment metabolism—may be subject to distortion as the result of an inborn metabolic error. Thus in this category fall such diverse disorders as the hemophilias, congenital agammaglobulinemia, the hemoglobinopathies, certain hemolytic anemias, Gilbert's disease, congenital methemoglobinemia, the porphyrias, a variety of renal tubular defects, cystinosis, oxalosis, Wilson's disease, primary gout, phenylketonuria, a variety of connective tissue defects, the lipidoses, essential hypercholesterolemia and hyperlipemia, several forms of sporadic familial cretinism, hypophosphatasia, galactosemia, glycogen storage disease, familial periodic paralysis, some of the progressive muscle dystrophies and myotonias, and many others. More doubtless remain to be uncovered.

The fault in inborn errors of metabolism apparently lies in the genetic deoxyribonucleic acid template from which enzymes and other proteins are generated. The resulting metabolic defect may be complete or partial. The functional deficiency may have profound clinical consequences if a critical activity is wholly blocked, particularly if adaptive alternative pathways are inadequate or it may not be clinically

overt, especially in the heterozygote. The anomaly may be apparent at birth or not until later in life (if at all) and then sometimes only if made manifest by environmental stresses.

The metabolic block resulting from inborn lack of a critical enzyme may become evident as absence of the end product of the affected reaction—for example melanin in albinism—or by abnormal accumulation of the substrate. To illustrate the latter instance in galactosemia there is a deficiency of galactose 1 phosphate uridylyl transferase, an enzyme necessary for the conversion of galactose 1 phosphate to glucose 1 phosphate, thus leading to accumulation of galactose 1 phosphate (and galactose) in the blood and tissues. Any one of several enzymes necessary to complete a particular sequence of metabolic reactions may be missing. A multiple pathogenesis of this kind has been established for glycogen storage disease, which may result from any one of three distinct inborn errors: lack of glucose 6 phosphatase, lack of "branching" enzyme necessary for normal glycogen synthesis, or lack of "debranching" enzyme required for glycogen degradation.

Some inborn deficiencies of metabolism become clinically manifest only with time and the complex interplay of diet, endocrine function, renal function, infection or other intercurrent disease, emotional stress and other poorly understood factors. The delay in appearance of a clinical deficit may be due to gradual storage of a metabolite. The principal clinical manifestations may be determined by secondary complications of the primary defect, as in the slow cumulative deposition of copper in selective areas of the brain, liver and kidney in Wilson's disease.

An interesting group of latent inborn errors of metabolism has been uncovered

as a result of study of the mechanisms of drug hypersensitivity. Sensitivity to primaquine and to the fava bean has been shown to be related to defective erythrocyte glucose 6-phosphate dehydrogenase. Untoward reactions to succinylcholine have been ascribed to inadequate pseudocholinesterase activity. Indeed as Haldane has pointed out it may be with the study of diatheses and idiosyncrasies differences of innate make up which do not necessarily lead to disease but may do so that future investigation in this field will be largely concerned.

The diversity of the clinical manifestations of the inborn errors of metabolism in part reflects the diversity of the specialized tissue functions which may preferentially be impaired. Thus the absence of a specific enzyme may particularly affect a function of the liver (homogentisic acid oxidase deficiency in alkaptonuria to cite one of many examples), bone (alkaline phosphatase deficiency in hypophosphatasia), red cells (a deficiency in erythrocyte glycolysis in hereditary spherocytosis), thyroid (a deficiency in the coupling of iodotyrosines in one form of sporadic familial cretinism), muscle (defective potassium utilization in periodic paralysis).

A number of inborn errors of metabolism are expressed principally or wholly by one or another deficiency in renal tubular function not infrequently occurring in a variety of combinations. For the most part these anomalies are characterized by defects in tubular reabsorption and presumably reflect deficiencies in enzyme components of transport systems resident chiefly in the proximal convolution. The increased renal clearance—whether of amino acids, hexoses, pentoses, phosphate, calcium, potassium, bicarbonate, water—is associated with low or low normal concentrations of the plasma component(s) in question in contrast to those extrarenal metabolic disorders in which excessive urinary excretion is due to overflow of an accumulation of some metabolite in the circulating fluids. The depletion which results from failure of renal conservation may of itself have untoward effects as in the development of rickets or osteomalacia in renal hypophosphatemia or muscle weakness following excessive urinary loss of potassium. In some instances the chief hazard is renal calculus formation when a constituent of low solubility is excreted in excess (cystinuria, oxaluria, idiopathic hypercalciuria). In the case of renal tubular acidosis the

tendency to calcium phosphate deposition as nephrocalcinosis or nephrolithiasis is favored by excessive urinary excretion of phosphate and calcium and is further facilitated by the accompanying defect in acidification of the urine.

Inborn errors of metabolism may affect the biosynthesis of proteins other than enzymes. Marfan's syndrome and the Ehlers-Danlos syndrome are examples of genetically derived deficiencies of specific structural elements of connective tissue. The genetically determined defects in the synthesis of the heme carrier protein globin abnormalities which are responsible for the various hemoglobinopathies have been particularly well studied. Ingram has shown that hemoglobins S and C differ from hemoglobin A only in the substitution of a single amino acid, valine or lysine respectively for glutamic acid at just one point in the long chain of amino acid sequences which constitute the globin molecule. As a consequence of these minute variations in composition the surface charges of the hemoglobin S and C molecules are altered sufficiently to permit separation from hemoglobin A by electrophoresis. The solitary defect in the globin moiety of hemoglobin S presumably is responsible also for the abnormal aggregation of hemoglobin S molecules within the red cells when oxygen is lost (sickling) and its far reaching clinical consequences. Similar minor changes in the composition of proteins possessing enzymatic properties might account for their apparent absence in inborn errors characterized by one or another metabolic block.

The study of the pathogenesis of inborn errors of metabolism has elucidated many pathways of normal as well as abnormal intermediary metabolism and will undoubtedly continue to be a rewarding area of investigation. Moreover such studies have thrown new light upon the basic aspects of the relationship of the deoxyribonucleic acids of the genes to the enzymic constitution of cells. Better insight into the nature of these disorders has made it possible further to initiate plans of therapy some of which have proved more effective than might have been supposed. It is not to be sure at present feasible to replace missing intracellular enzymes but the effects of deficiencies can be circumvented in some instances whether by dietary regulation (galactosemia, phenylketonuria, essential hyperlipemia for example), drugs (congenital methemoglobinemia, gout, Wilson's

disease) or simple replacement of depleted electrolytes or metabolites (as in a variety of renal tubular deficiencies)

## CONGENITAL METHEMOGLOBINEMIA

**Definition** Congenital methemoglobinemia is characterized by abnormal accumulation of methemoglobin in the blood as a consequence of an inherent inability to reduce the ferric iron of methemoglobin which is incapable of oxygenation to the ferrous iron of hemoglobin. In severe cases methemoglobin may comprise 30 per cent or more of the total pigment (normally less than 1 per cent) thus resulting in hypoxemia due to inadequate transport and availability of oxygen.

**Etiology** There is no history of exposure to the various chemical agents responsible for acquired methemoglobinemia (see p 505). However since the red blood cells of the newborn normally do not yet contain their full quota of the enzyme system required for reduction of methemoglobin to hemoglobin the infant is peculiarly vulnerable to such agents.

There are at least two separate forms of congenital methemoglobinemia due to different inborn errors which block reduction of methemoglobin by distinct metabolic pathways. In one group of cases there appears to be according to Gibson a specific deficiency in erythrocyte coenzyme factor I (diaphorase a flavoprotein) which is necessary for the enzymatic conversion of methemoglobin to hemoglobin occurring normally in the red blood cells. This process catalyzed by methemoglobin reductase depends upon the proper utilization of glucose or lactate and requires a sufficient supply of reduced diphosphopyridine nucleotide (DPN H). Another group of cases first differentiated by Horlein and Weber is characterized according to Gerald and others by the presence of methemoglobin M. This is an abnormal methemoglobin with distinct spectral characteristics associated with the presence of abnormal hemoglobin M.

The trait is generally believed to be transmitted as a recessive in the first group of cases and probably as a dominant in the second. The differences in globins may also explain discrepancies in the effect of methemoglobinemia on the oxyhemoglobin dissociation curve which is shifted to the left in some (but not all) cases thus adversely affecting release of oxygen from oxyhemoglobin as well as the oxygen capacity.

**Symptoms and Signs** If the defect is sufficiently pronounced congenital methemoglobinemia may be manifest at birth or early in life as a diffuse persistent gray or slate blue cyanosis. The contrast between the deep cyanosis at rest and the absence of signs or symptoms of cardiac or respiratory abnormalities should suggest the diagnosis particularly when a familial incidence can be established. Exertion however often elicits fatigability, dizziness, dyspnea, tachycardia and severe headache. Clubbing of the fingers does not occur. In severe cases compensatory polycythemia develops with injection of the conjunctivas, engorgement of the retinal veins and other typical manifestations.

The venous blood is brown and fails to recover its normal color after prolonged shaking in air. The oxygen capacity of arterial blood is reduced despite a high hematocrit; the oxygen content is proportionately low. Spectroscopic examination reveals the presence of excessive amounts of methemoglobin with an absorption band at  $630 \mu$  but this is not observed in the case of methemoglobin M.

**Treatment** Recognition of congenital methemoglobinemia is important because confusion with surgically amenable congenital heart disease may lead to needless exploration and because effective treatment is available once the proper diagnosis has been established. Continued administration of methylene blue by mouth will restore the oxygen capacity of the blood and maintain the patient free of cyanosis, headache and associated symptoms. Eder and his co-workers found that daily doses of 240 mg in enteric-coated tablets alleviated all signs and symptoms including polycythemia and reticulocytosis and were well tolerated. Excessive amounts should not be used because methylene blue in massive dosage causes methemoglobin formation. Ascorbic acid in daily oral doses of 300 to 500 mg is also efficacious, probably exerting a direct reducing action on methemoglobin.

The prognosis as to life is good.

## THE GLYCOGEN STORAGE DISEASES

(Glycogenosis von Gierke's Disease)

**Definition** Glycogen storage disease is a composite term referring to a group of distinct inborn errors of carbohydrate metabolism characterized by excessive deposition of glycogen in tissues usually associated with an anomaly of one or another enzyme system concerned with glycogen degradation or synthesis. In the hepatorenal form *von Gierke's disease* glycogen storage occurs chiefly in the liver and kidney. In *generalized glycogenosis* the distribution of excessive glycogen is more diffuse but is preponderantly in cardiac and skeletal muscle. This rare disorder is often referred to as the cardiac form of glycogen storage disease. A possibly related form of glycogen disease a myopathy due to inability of the skeletal musculature to utilize muscle glycogen properly has been described by McArdle as another probable inborn error of carbohydrate metabolism (*McArdle syndrome*).

**Etiology** Cori has shown that in most cases of the hepatorenal type the excessive liver glycogen is of normal molecular structure but there is a deficiency of the liver enzyme glucose 6 phosphatase. Hence glycogen can be formed from glucose but glucose 6 phosphate derived from liver glycogen or from ingested glucose through the action of hexokinase cannot be broken down again to regenerate glucose when required. In occasional cases of *von Gierke's disease* there is no deficiency of glucose 6 phosphatase but the metabolic error appears to be a lack of branching enzyme (1,4 → 1,6 transglucosidase) or of debranching enzyme (amylase 1,6 glucosidase). These deficiencies are associated with abnormal molecular structure of glycogen and inadequate utilization for glucose formation because of inaccessibility of the major part of the glycogen molecule to the action of phosphorylase. In generalized

glycogenosis the metabolic error has not yet been identified—there appears to be neither abnormal glycogen synthesis nor an absence of specific glucose 6 phosphatase. In the *McArdle syndrome* there would seem to be a deficiency of 1,3 diphosphoglycerate dehydrogenase in skeletal muscle.

**Symptoms and Signs** *Von Gierke's disease* usually becomes manifest in infancy or early childhood as a problem in feeding or because of undue prominence of the abdomen or delayed growth. The most characteristic physical finding usually present in infancy is marked hepatomegaly due to the excessive deposits of glycogen often associated with a considerable increase in neutral fat. Jaundice may appear. The spleen ordinarily is not enlarged.

Because of the limited availability of glucose upon demand hypoglycemia and ketosis develop particularly in the fasting state. The symptoms of hypoglycemia may dominate the picture: shock or generalized convulsions occurring typically in the early morning hours. The realization that frequent feedings allay these symptoms may later result in obesity. There is usually delay in growth and development of afflicted children.

*Generalized glycogenosis* is characterized by very marked globular enlargement of the heart in infants with progressive and refractory cardiac failure leading to death in the early weeks or months of life. This is due to massive glycogen infiltration of the ventricular musculature giving a lace work appearance to the myocardium. There is associated cyanosis, dyspnea and malnutrition. Macroglossia due to glycogen storage in the musculature of the tongue may be striking. Glycogen storage in the renal tubules may be associated with generalized aminoaciduria and other reabsorptive defects.

In the *McArdle syndrome* no abnormality is apparent other than a myopathy characterized by pain, stiffness and weakness with prolonged contracture of the skeletal muscles upon moderate exercise. There is no demonstrable disability of the muscles at rest.

**Diagnosis** Liver puncture biopsy offers the most direct method of diagnosis in the hepatorenal form of glycogen storage disease. The liver cells engorged with glycogen present a characteristic plant cell appearance and give the typical staining reactions for glycogen. A deficiency of glucose 6 phosphatase may be inferred if the glycogen disappears at a normal rate upon incubation with normal liver homoge-

nate The presence of excessive neutral fat may lead to confusion with hypertrophic steatosis or fatty liver associated with diabetes mellitus

Von Gierke's disease should be suspected in infants or children who have marked enlargement of the liver hypoglycemia and ketosis or rapid development of these manifestations when food is withheld and subnormal or no response of the blood sugar to injection of epinephrine (due to unavailability of liver glycogen stores) Additional findings are low serum carbon dioxide combining power ketonuria increased serum glycogen delayed rise in blood sugar after glucose tolerance tests and low curves with rapid fall in levulose and galactose tolerance tests Hyperlipemia and hypercholesterolemia may be so marked as to cause diagnostic difficulties

The cardiomegaly of generalized glycogenosis in infants may simulate subendocardial fibroelastosis and multiple rhabdomyomas of the heart the latter usually associated with tuberous sclerosis of the brain Definitive diagnosis can be made only at necropsy by histochemical or chemical demonstration of glycogen in the tissues

**Treatment** Treatment in the hepatorenal form of glycogen storage disease is directed toward improvement of nutrition and correction of hypoglycemia and acidosis This is accomplished by frequent feedings including night feedings and the use of glucose or Dexin between meals An extra high protein meal of ground beef and bread late at night has been found helpful Ulstrom et al found corticotropin useful for this purpose Gradual symptomatic improvement as the children grow older is the rule although hepatomegaly usually persists

## GALACTOSEMIA

**Definition** Galactosemia is an inborn error of metabolism characterized by defi-

ciency of an enzyme galactose 1 phosphate uridylyl transferase necessary for formation of glucose 1 phosphate from galactose 1 phosphate in the conversion of galactose to glucose occurring predominantly in the liver In consequence of this metabolic block galactose and galactose 1 phosphate accumulate in the blood and tissues appearing also in excess in the urine after feedings of milk or other foods containing lactose or galactose

**Etiology** The pattern of inheritance has not been fully elucidated In affected families the trait in some otherwise normal members may be demonstrable only by an abnormal galactose tolerance test and minor discomforts after ingestion of milk

The chief organs of galactose storage are the liver and the spleen Cataracts develop early as in experimental animals fed a high galactose diet Ensuing brain damage may be related to disturbed galactolipid biosynthesis Deposition of galactose in the renal tubules seems to be responsible for the appearance of tubular reabsorptive defects The erythrocytes also are deficient in the transferase and accumulate galactose and galactose 1 phosphate but without obvious ill effects on this account

**Signs and Symptoms** The infant is normal at birth but soon becomes a feeding problem with vomiting diarrhea and failure to thrive The abdomen is prominent because of distention and increasing hepatomegaly often with jaundice and occasionally with ascites Cirrhosis may develop Mental retardation is a common accompaniment Cataracts appear in more than half of those markedly affected In less severe cases the progress of events is slower a matter of months and mild cases escape with only minor gastrointestinal complaints

Proteinuria is the rule aminoaciduria hyperchloremic acidosis and hypokalemia may develop The pathognomonic feature however is marked galactosemia and galactosuria after ingestion of lactose or galactose Glucose levels in the blood are apt to be reduced and ketosis may occur with vomiting and dehydration

**Treatment** The key to management is complete exclusion of all milk and other foods containing lactose or galactose Soy milk preparations are frequently employed but may contain polygalactose Holzel and others recommend a milk free diet consisting of eggs sugar margarine and rice flour with appropriate vitamin and mineral supplements If this diet can be instituted early and maintained through the

first three years of life it is possible to prevent the development of liver damage cataract and mental retardation and to effect improvement if these complications are already present

## RENAL GLYCOSURIA

("True Renal Diabetes")

True renal diabetes is defined as an isolated inborn defect in renal tubular reabsorption of glucose characterized by unremitting urinary excretion of glucose in substantial amounts in association with low or low normal fasting blood sugar and normal glucose tolerance. The condition should be differentiated from overflow glycosuria in hyperglycemic states particularly diabetes mellitus alimentary glycosuria due to excessive glucose intake or a lowering of the threshold for glucose within the limits of normal variation and acquired renal glycosuria due to nephrotoxic agents. Renal glycosuria may occur in association with other renal tubular defects in a variety of inborn errors of metabolism and may be acquired as a result of factors which lower the threshold for glucose.

Analysis of clearance data in patients with true renal diabetes indicates considerable variation in the degree of decline in the Tm for glucose. In some the evidence suggests heterogeneity of the nephron population in other the nephrons appear to be uniformly defective. It is not clear whether this implies a deficiency in some as yet unidentified enzyme system for tubular transport of glucose.

True renal diabetes is relatively rare. It appears very early in life and is compatible with good health and long life showing no predilection for the development of diabetes mellitus. No treatment is required.

## FRUCTOSURIA

In essential fructosuria an inborn error of metabolism blood fructose levels are excessive and renal tubular reabsorption of fructose is inadequate to remove fructose altogether from the glomerular filtrate. The principal defect may be a deficiency of fructokinase an enzyme that catalyzes the formation of fructose 1 phosphate from fructose and ATP.

After ingestion or intravenous infusion of fructose appreciable amounts may appear in the urine of normal persons ("alimentary fructosuria") larger quantities in the presence of severe liver damage. Because fructose reduces the reagents ordinarily employed in testing urine for sugar fructosuria is often mistaken for glucosuria. The disorder involves no disability although a considerable proportion of ingested carbohydrate may be lost from diets rich in fruits or sucrose.

## PENTOSURIA

Pentosuria is a rare inborn error of metabolism characterized by excessive excretion of L xylulose a normal pentose metabolite derived from L gulonolactone and ordinarily progressing through D xylulose and the pentose cycle to glucose. Essential pentosuria is to be distinguished from alimentary pentosuria which may occur in normal persons after the ingestion of large amounts of vegetable gums fruits or berries rich in pentosans. The condition involves no disabilities but may be confused with glycosuria because of the reducing properties of the pentoses in question. The distinction may be made by means of the orcinol reaction lack of fermentation with yeast and preparation of the phenyl osazone derivative.

## OXALOSIS

Oxalosis is a rare apparently inborn error of metabolism characterized by excessive biosynthesis of oxalic acid which is widely deposited in the tissues as the insoluble calcium salt. Renal calculi and

nephrocalcinosis are common manifestations. Bone marrow deposits may be extensive causing generalized osteoporosis with typical metaphyseal zones of rarefaction in the long bones. Death ensues early in life usually as a result of renal insufficiency.

The urinary excretion of calcium oxalate in oxalosis usually is not markedly increased unlike the oxaluria resulting from excessive dietary intake of oxalate or occurring in primary hyperoxaluria.

## CYSTINOSIS

(Cystine Storage Disease, Lignac's Disease, Lignac-Fanconi Syndrome)

Cystinosis is an inborn error of cystine metabolism characterized by the deposition of cystine in the tissues particularly in the reticuloendothelial cells of the bone marrow, liver, spleen and lymph nodes in the cornea (where the crystals can be seen by slit lamp examination thus affording the diagnosis) subcutaneous tissues and kidneys. The deposits in the renal tubules are held responsible for the development in infancy of the full-blown multiple tubular deficiencies of the Lignac-Fanconi syndrome (q.v.) with accompanying rickets, retardation of growth and development, dehydration, polyuria and eventual glomerular insufficiency. Unlike cystinuria, the urinary excretion of cystine is not inordinate. Bickel has described improvement in the tubular and skeletal defects with administration of large doses of vitamin D in some cases, but the prognosis generally is poor. In severe cases death is likely to occur in infancy, often in uremia.

## THE AMINOACIDURIAS

Chromatographic analysis has revealed that the blood plasma normally contains small amounts of more than 20 amino

acids in free and conjugated form. These amino acids are filterable at the glomerulus but are largely reabsorbed in the tubules, appearing in the urine in trace amounts if at all. Only 1 to 2 per cent of the total urine nitrogen is made up of urine amino nitrogen, chiefly glycine, histidine, taurine, alanine, serine, asparagine and threonine. So limited however is the normal tubular reabsorptive capacity for amino acids that overflow into the urine is apt to occur when there is a substantial rise in the concentration of amino acids in the plasma and consequent augmentation of the filtered load. Overflow aminoaciduria may involve many amino acids as in hepatic insufficiency with general impairment of urea formation from amino acids. Or a single amino acid and its derivatives may appear in excess in the urine as in phenylketonuria. In this disorder a specific inborn deficiency of phenylalanine hydroxylase in the liver with resultant block of the conversion of phenylalanine to tyrosine leads to accumulation in the plasma of phenylalanine and its oxidation products, phenylpyruvic and phenyllactic acids, and all these acids spill over into the urine.

Aminoaciduria may occur also as a consequence of defective tubular reabsorption of amino acids, resulting in excessive rates of clearance with characteristically low or at most normal plasma amino acid concentrations. Such tubular reabsorptive defects may be limited to a single amino acid as in glycinuria or to a selective group of amino acids as in cystinuria or may include a wide variety of amino acids and indeed extend to other metabolites and electrolytes as in the Fanconi syndrome (see p 581). The defects in tubular reabsorption of amino acids may be inborn or acquired. They may be acquired in infants with rickets due to vitamin D deficiency (the tubular defects disappearing after treatment with vitamin D) and in vitamin C deficiency. Exposure to heavy metals such as lead, uranium and cadmium and to other toxic agents such as Lysol and maleic acid may lead to aminoaciduria and associated glycosuria and phosphaturia. Tubular reabsorptive defects including aminoaciduria apparently may be acquired as an indirect result of inborn errors of metabolism, only secondarily affecting the kidneys, for example deposition in the renal tubules of copper in Wilson's disease or of glycogen in glycogen storage disease or of cystine in cystinosis. Under such circumstances it may be exceedingly difficult to determine whether the aminoaciduria

first three years of life it is possible to prevent the development of liver damage, cataract and mental retardation and to effect improvement if these complications are already present

## THE AMINOACIDURIAS

Chromatographic analysis has revealed that the blood plasma normally contains small amounts of more than 20 amino

acids in free and conjugated form. These amino acids are filterable at the glomerulus but are largely reabsorbed in the tubules appearing in the urine in trace amounts if at all. Only 1 to 2 per cent of the total urine nitrogen is made up of urine amino nitrogen chiefly glycine, histidine, taurine, alanine, serine, asparagine and threonine. So limited however is the normal tubular reabsorptive capacity for amino acids that overflow into the urine is apt to occur when there is a substantial rise in the concentration of amino acids in the plasma and consequent augmentation of the filtered load. Overflow aminoaciduria may involve many amino acids as in hepatic insufficiency with general impairment of urea formation from amino acids. Or a single amino acid and its derivatives may appear in excess in the urine as in phenylketonuria. In this disorder a specific inborn deficiency of phenylalanine hydroxylase in the liver with resultant block of the conversion of phenylalanine to tyrosine leads to accumulation in the plasma of phenylalanine and its oxidation products, phenylpyruvic and phenyllactic acids and all these acids spill over into the urine.

Aminoaciduria may occur also as a consequence of defective tubular reabsorption of amino acids resulting in excessive rates of clearance with characteristically low or at most normal plasma amino concentrations. Such tubular reabsorptive defects may be limited to a single amino acid as in glycineuria or to a selective group of amino acids as in cystinuria or may include a wide variety of amino acids and indeed extend to other metabolites and electrolytes as in the Fanconi syndrome (see p 581). The defects in tubular reabsorption of amino acids may be inborn or acquired. They may be acquired in infants with rickets due to vitamin D deficiency (the tubular defects disappearing after treatment with vitamin D) and in vitamin C deficiency. Exposure to heavy metals such as lead, uranium and cadmium and to other toxic agents such as Lysol and maleic acid may lead to aminoaciduria and associated glycosuria and phosphaturia. Tubular reabsorptive defects including aminoaciduria apparently may be acquired as an indirect result of inborn errors of metabolism only secondarily affecting the kidneys, for example deposition in the renal tubules of copper in Wilson's disease or of cystine in cystinosis. Under such circumstances it may be exceedingly difficult to determine whether the aminoaciduria

is ■ primary or secondary manifestation of the metabolic error

**Cystinuria** Of the isolated aminoacidurias due to an inborn error primarily affecting tubular reabsorption that designated cystinuria is characterized in the homozygote by the excessive renal clearance jointly and specifically of four amino acids cystine lysine arginine and ornithine There is no intrinsic block in the intermediary metabolism of cystine nor are tissue deposits of cystine found such as characterize cystinosis (see p 579) The plasma levels of all four amino acids affected are reduced The depletion of these amino acids does not seem to have any deleterious effect and the disorder is compatible with health and long life However the presence in the urine of excessive quantities of cystine which is difficultly soluble at acid or neutral pH favors the formation of cystine calculus and this represents the chief hazard The presence of increased amounts of cystine in the urine can be detected by the cyanide nitroprusside reaction

In prevention and treatment of stone it is important to encourage a large intake of fluid during the night also in order to maintain urine volumes copious enough to hold the cystine in solution Alkalinizing agents are of dubious value because the urine ordinarily cannot be made sufficiently alkaline to affect the solubility of cystine significantly The efficacy of dietary restriction of foods rich in methionine and cysteine which are converted to cystine is still under study but it is apparent that the protein intake should be sufficient for growth and/or maintenance

**Glycinuria** Excessive urinary excretion of glycine occurs in many generalized aminoacidurias but deVries *et al* have called attention to a genetically determined defect specifically of the renal tubular reabsorption of glycine unaccompanied by any other abnormality in renal function The condition ■ consistent with good health save for a predisposition to renal calculus formation The stone in one case examined proved to be composed almost entirely of calcium oxalate glycine also was present but in very small amount

Another example of an inheritable defect in renal tubular reabsorption limited to a single amino acid is  $\beta$ -aminoisobutyric aciduria This anomaly seems to have no clinical consequence

## FANCONI SYNDROME

(de Toni Debré Fanconi Syndrome Lignac Fanconi Syndrome)

**Definition** "Fanconi syndrome ■ an inclusive term used to designate ■ variable complex of multiple defects in renal tubular function characteristically comprising massive generalized aminociduria renal glycosuria and renal hypophosphatemia Except in late or complicated cases glomerular filtration ■ little impaired or not at all In the familial type encountered particularly in infants and children the symptom complex includes stunted growth rickets resistant to vitamin D acidosis dehydration and associated cystinosis in some instances The heterogeneous adult type which may be due to inborn errors or acquired is not related to cystinosis and ■ apt to be less severe but more inclusive variously affecting also the renal excretion of water potassium and urate and occasionally overlapping to some extent with renal tubular acidosis When symptomatic the adult form is usually manifested by osteomalacia sometimes by hypokalemic muscle weakness

**Etiology** Microdissection of nephrons in the Fanconi syndrome by Darmady and co workers has revealed an anomaly of the most proximal segment of the convoluted tubules which is much shortened and joined to the glomerulus by a narrow elongated "swan's neck" This finding is consistent with renal function studies implicating the proximal convolution as the chief site of the tubular deficiencies It is not clear however whether the "swan's neck" anomaly is to be regarded as ■ primary or secondary cause of the defects in tubular function even in the genetically determined forms of the Fanconi syndrome Bickel's observations in the infantile type associated with cystinosis indicate that the tubular reabsorptive defects are not present at birth but occur subsequently as the tissue deposits of cystine accumulate it is implied that cystine infiltrates into the tubular cells and thus is indirectly responsible for the development of the Fanconi syndrome

The adult form of Fanconi syndrome clearly has a multiple genesis When in born the disorder is transmitted according

deVries A Kochwa S Lazebnik J Frank M and Djaldetti M Glycinuria a Hereditary Dis

to Dent and Harris as a recessive trait. The characteristic tubular reabsorptive defects may, however, be acquired in part or in whole in a variety of circumstances including exposure to heavy metals such as lead, uranium and cadmium or to toxic compounds such as Lysol. Deposition of copper in the tubules in Wilson's disease or of abnormal proteins in multiple myeloma or of carbohydrate in glycogen storage disease and galactosemia in rickets due to vitamin D deficiency and in vitamin C deficiency. The etiological relationship in some of these circumstances has been demonstrated by disappearance of the tubular insufficiencies when the primary cause is treated.

**Symptoms and Signs** In the infantile type with cystinosis the children are severely affected. They are malnourished and dehydrated. There is marked polyuria with isosthenuria and excessive thirst. Gastrointestinal upsets and muscle weakness are common. Resistance to intercurrent infections is impaired. Growth and development are delayed. The characteristic deformities of low phosphorus rickets, relatively resistant to vitamin D, are present. Progressive glomerular insufficiency is a common late sequel often with termination in uremia. In full-blown cases survival to puberty is exceptional.

The clinical manifestations in the adult are more insidious. They are apt to be ushered in and dominated by the manifestations of osteomalacia. These include pain in the weight-bearing bones, difficulty in walking and a waddling gait, pathological fractures and sometimes eventual incapacitation. Roentgenograms reveal the typical pseudofractures of Milkman's syndrome with symmetrical infractions of bone, particularly in the pelvis, scapulae, femurs, humeri and ribs. Nephrocalcinosis does not occur; renal calculi, but rarely. In some cases weakness and weight loss are prominent and one must be alert to the development of recurrent episodes of hypokalemic paralyses.

The characteristic urinary losses of amino acids, glucose, phosphate, potassium and urate are associated with low or low normal plasma concentrations of these components. An increase in serum alkaline phosphatase accompanies the presence of osteomalacia. A mild systemic acidosis is often present. The urine is apt to be alkaline and occasionally an associated defect in acidification of the urine can be demonstrated.

**Treatment** The response to an alkalizing

regimen often is gratifying. Shohl's citrate mixture in doses of 30 ml three times daily usually restores electrolyte balance to this potassium citrate may be added when hypokalemia is pronounced. Healing of rickets and osteomalacia requires large doses of vitamin D (50 000 units or more daily) and calcium salts but overdosage (hypercalcemia and its clinical manifestations) should be avoided. The outlook in the adult form of Fanconi syndrome is favorable but relapse is the rule if maintenance therapy is discontinued.

## RENAL HYPOPHOSPHATEMIA

(Phosphate Diabetes, Vitamin D Resistant Rickets)

**Definition** Renal hypophosphatemia is characterized by a renal tubular defect in reabsorption of phosphate. The loss of phosphate in the urine results in a decline in serum inorganic phosphate concentration and a predilection to vitamin D resistant rickets in children, osteomalacia in adults.

**Etiology** The isolated tubular defect in reabsorption of phosphate when inborn is transmitted as a dominant according to Winters et al as a sex-linked dominant. Renal hypophosphatemia occurs also in association with other inborn defects, notably renal glycosuria, aminoaciduria (Fanconi syndrome) and renal tubular acidosis and may accompany neurofibromatosis. Deficient tubular reabsorption of phosphate may also be acquired usually in conjunction with other tubular defects due to renal damage as a complication of an unrelated inborn error of metabolism (Wilson's disease for example) or from exposure to heavy metals in the environment.

**Signs and Symptoms** When the hypophosphatemia is clinically expressed the skeletal manifestations of rickets or osteomalacia (Milkman's syndrome) are usually more pronounced in male carriers of the trait. In diagnosis, familial incidence de-

velopment of the skeletal disorder despite a diet adequate in vitamin D and resistance to vitamin D therapy in ordinarily effective dosage exclude vitamin D deficiency and point to renal hypophosphatemia which can be established by clearance measurements. Examination of the urine for glucose and amino acids will determine whether the tubular reabsorptive defect is limited to phosphate or is part of a more diffuse tubular anomaly.

*Hypophosphatasia* causes a disturbance in calcification of cartilage and bone which may simulate the rickets of renal hypophosphatemia. This disorder is an inborn error in alkaline phosphatase production in the tissues and is characterized by low serum alkaline phosphatase (in contrast to the increase observed in renal hypophosphatemia with skeletal lesions), normal serum inorganic phosphate, hypercalcemia and urinary excretion of phosphorylethanolamine (apparently a natural substrate of alkaline phosphatase). The metabolic error does not appear to involve renal function. There is no beneficial response to vitamin D but administration of corticosteroids has been helpful in some cases.

**Treatment.** Overt rickets or osteomalacia due to renal hypophosphatemia requires massive doses of vitamin D before a curative action can be obtained. The daily therapeutic requirement varies from 50 000 to several hundred thousand or more units and must be determined by the individual response.

## RENAL TUBULAR ACIDOSIS

(Renal Hyperchloremic Acidosis)

**Definition.** Renal tubular acidosis is characterized by defective renal tubular function manifested by excretion of inappropriately alkaline or insufficiently acid urine, hyperchloremic acidosis, hypophosphatemia and intermittent hypokalemia. Glomerular filtration is not significantly impaired in un-

complicated cases. Renal glycosuria and aminoaciduria characteristically do not occur.

**Etiology.** The basic functional abnormality appears to reside in the impaired capacity of the kidney to acidify the urine from this most of the other manifestations of the disorder can reasonably be derived. The precise nature of the primary urinary defect in acidification however is still in doubt. It has been variously ascribed to deficient reabsorption of bicarbonate in the proximal tubule, an inherent defect in ammonia production, perhaps in tubular glutaminase activity, an intrinsic error in the mechanism by which the tubular cell secretes hydrogen ion in exchange for sodium ions of the tubular urine, and an inherent or drug induced deficiency of renal tubular carbonic anhydrase suggested by the many similarities between the naturally occurring disorder and that produced by protracted administration of acetazolamide (alkaline urine, hyperchloremic acidosis, renal calculus formation). Appropriate loading and other tests however have not as yet fully substantiated any one of these several hypotheses.

It is not clear whether variations in kind or in degree of defective tubular function are responsible for the diversity of clinical manifestations of renal tubular acidosis and whether the disorder encountered in young adults has the same genesis as that occurring in infants. A familial incidence has been demonstrated in some cases implying an inherent tubular deficiency in at least these instances. Tubular damage due to pyelonephritis has been incriminated but appears to be secondary. Occurrence in infants may be related in part to delayed renal development since the urinary abnormalities may ultimately disappear.

**Symptoms and Signs.** The paradoxical excretion of an alkaline or only slightly acid urine in the face of a metabolic acidosis should direct attention to this syndrome. There is apt to be diminished ability to concentrate the urine which may be excreted in such copious quantities as to cause marked dehydration notably in affected infants despite polydipsia. The serum bicarbonate is reduced, the serum chloride increased, the serum phosphate and potassium levels are both low, the serum alkaline phosphatase is increased when skeletal lesions are present.

Three complications are particularly prone to occur in the adult type of the disease: *nephrocalcinosis* or *renal calculus*.

formation osteomalacia and profound muscle weakness. Deposition of calcium within the kidney substance or as calculus with recurrent ureteral colic is favored by the alkalinity of the urine and possibly by reduced urinary citrate; there is little to support the hypothesis of secondary hyperparathyroidism. Pyelonephritis often supervenes sometimes with progressive glomerular insufficiency. The hypophosphatemia results from loss of phosphate in the urine and presumably is responsible for the appearance in the adult of osteomalacia with the characteristic manifestations of Milkman's syndrome and in children of rickets refractory to vitamin D. There may be disturbances in skeletal growth or in the adult in gait. Spontaneous fractures may occur. Muscle stiffness or weakness with episodic periods of paralysis may be a presenting symptom as a consequence of potassium depletion due also to excessive loss in the urine. The undue urinary excretion of potassium presumably is a reflection of the defective hydrogen ion secretion in acidification of the urine. It is possible that renal tubular damage associated with potassium depletion may be superimposed upon the initial defect in some cases.

As already mentioned administration of carbonic anhydrase inhibitors such as acetazolamide may simulate the metabolic disturbances characteristic of renal tubular acidosis. Hyperchloremic acidosis with somewhat similar symptomatology occurs also after ureterostigmoidostomy.

**Treatment.** The response to appropriate therapy is gratifying. Replacement of lost base by daily oral administration of an alkalinizing mixture of citrates effectively relieves the acidosis and restores electrolyte balance in most cases. The manifestations of osteomalacia or rickets respond gratifyingly to vitamin D in doses of 50,000 units a day and calcium salts by mouth to avoid further renal damage; however these should not be pushed to hypercalcemia and should be discontinued upon healing of the skeletal lesions. Hypokalemic episodes require administration of potassium salts. The use of sulfonamides which inhibit carbonic anhydrase should be avoided since exacerbation of symptoms may occur.

#### ALCAPTONURIA AND OCHRONOSIS\*

**Definition.** Alkaptonuria is a rare disorder of the metabolism of the amino acids tyrosine and phenylalanine characterized by the excretion of homogentisic acid in the urine.

**Pathogenesis.** It occurs most commonly in males and is transmitted according to recent evidence as a dominant trait with incomplete penetrance, not as a recessive as previously believed. The metabolic block is complete and the amount of homogentisic acid excreted is proportional to the amount of protein catabolized. Homogentisic acid is formed in the normal course of catabolism of tyrosine and phenylalanine but normally is wholly degraded by homogentisic acid oxidase and does not appear in the urine. Recent studies by LaDu et al. on liver tissue from an alkaptonuric patient have shown that homogentisic acid oxidase is completely lacking in this disorder. There appear to be no other defects in the metabolism of tyrosine and phenylalanine.

**Diagnosis.** The diagnosis is often suggested early in life by diapers or linen stained black or brown by urine and by a family history of alkaptonuria.

**Urine.** The color of the urine is normal when acid and freshly excreted; when alkaline it may be dark. When alkali is added it turns black. It reduces Benedict's solution imparting a brown or black color to the supernatant fluid. This appearance should suggest the presence of an abnormal reducing substance other than glucose. Further identification can be made by more specific chemical tests and if the diagnosis still remains in doubt isolation of homogentisic acid from the urine will establish the diagnosis with certainty.

**Ochronosis.** Ochronosis is a clinical state characterized by the deposition of bluish black pigment in the cartilages, tendons and other types of connective tissue. The term ochronosis was derived from the ochre like color of the pigment on histological examination. In time probably all alkaptonuric persons develop some degree of pigmentation but the intensity and

The author wishes to express his deep appreciation to Dr. Morton Galdston for his valuable assistance in the revision of this article.

distribution as seen clinically varies considerably. In its fully developed form as seen in older alkaptonurics it is manifested by a patch of light brown or slate gray pigment in the sclerae on either side of the corneal limbus by a bluish discoloration of the external ears, nasal cartilage and superficial tendons of the hands and brown pigmentation in the skin, cerumen, sweat and the nails. The pigmented ears are opaque to the transmission of light.

The term *ochronosis* also applies to similar pigmentation associated with clinical conditions other than alkaptonuria. It was formerly seen after long continued application of phenol dressings to leg ulcers and it may occur in association with melanuria. The pigmentation observed after the use of phenol gradually recedes after the causative agent is discontinued. In contrast the pigmentation associated with alkaptonuria by virtue of the permanence of the metabolic disturbance is persistent and progressive.

In spite of the similarity in distribution and appearance of the ochronotic pigments, their origin is distinct. Alkaptonuric pigment is a derivative of homogentisic acid, whereas melanotic pigment is derived from 3,4-dihydroxyphenylalanine (dopa). The enzyme tyrosinase catalyzes the oxidation of dopa to melanin, but there is no reason to believe it is also involved in the polymerization of homogentisic acid to the ochronotic pigment. The pathway by which phenol is converted to ochronotic pigment is unknown.

**Arthritis.** Pigment deposition in joint cartilages is accompanied by degenerative changes and arthritis. The severity of the arthritis is not necessarily proportional to the degree of joint pigmentation, but arthritis may be the chief complaint of middle-aged alkaptonurics and it is a prominent feature of the condition. The joints usually affected are the hip, knee, shoulder and the spine. The rate of progression of the arthritis and the intensity of symptoms vary widely among different patients.

**Röntgenographic Findings.** Roentgenographic examination of the spine may show the presence of intense calcification of the intervertebral disks, which is characteristic of the disease. In addition, degenerative osteoarthritic changes are generally apparent in the involved joints. Calcific deposits are commonly seen in muscle tendons about the large joints. Stones may be demonstrated in the urinary bladder, prostate gland and the urethra.

**Prognosis.** The disease does not apparently decrease life expectancy. Except for the passage of black urine and the appearance of pigmentation in the second and third decades, as described under *Ochronosis*, patients are relatively free of symptoms until the onset of arthritis in middle age.

**Treatment.** No specific treatment is available for alkaptonuria or for *ochronosis* associated with it. Scorbutic guinea pigs fed phenylalanine or tyrosine excrete homogentisic acid in the urine and this defect is corrected by vitamin C. In contrast, clinical alkaptonuria is not due to a vitamin C deficiency and this vitamin has no effect on the metabolic defect. The only effect of vitamin C in clinical alkaptonuria is that it delays to some degree the darkening of the urine because of its strong reducing properties. A restriction of dietary protein has been advocated since this decreases the amount of homogentisic acid excreted per day and might theoretically decrease the rate of development of *ochronosis*. The arthritis resembles osteoarthritis and should be treated similarly. It does not respond favorably to agents found effective in rheumatoid arthritis, such as ACTH, cortisone and phenylbutazone.

## PHENILPYRUVIC OLIGOPHRENIA

(Phenylpyruvic Amentia, Phenylketonuria)

**Definition and Genetics.** Phenylpyruvic oligophrenia, first described by Folling in 1934, is a hereditary disease characterized by mental deficiency and by a metabolic aberration, failure in the hydroxylation of phenylalanine to tyrosine, manifested by urinary excretion of phenylpyruvic acid. Genetic studies have proved that the condition is transmitted as a simple mendelian recessive trait. Jervis studied 125 families and found 52 in which more than one

sibling was affected Penrose studied the families of 203 initial cases and found that 129 of 638 siblings were affected in 30 of the 203 families the parents were first cousins

**Incidence** The reported incidence varies in different countries and probably depends on the awareness of investigators In the United States and Great Britain where extensive genetic clinical and metabolic studies have been conducted the over all incidence is about 1 25 000 and 1 50 000 respectively in institutions for the feeble minded 0.3 to 0.8 per cent of inmates of all ages In Norway Folling and his associates discovered 34 cases or 1.4 per cent of about 2400 mental defectives tested Swiss investigators found only 3 cases in tests on about 2500 mental defectives One case has been reported in a Jewish child The disease is extremely rare in non white persons

**Clinical Findings** The most striking clinical finding is mental deficiency generally of severe degree Psychometric tests of institutionalized phenylketonurics place about 60 to 65 per cent in the idiot range (IQ below 20) and 30 to 35 per cent in the imbecile range (IQ 20 to 50) Several patients have been reported with IQ's over 80 Probably more with normal or nearly normal intelligence will be discovered outside of institutions

Patients usually come to the physician's attention by one of three routes (1) search among institutionalized mental defectives (2) detection of the urinary abnormality in siblings of known cases or by routine ferric chloride test in "well baby" examinations or (3) symptoms such as slow development lethargy or convulsions The infants may appear normal at birth but in a few weeks show lack of interest in surroundings and delay in motor development They usually are good natured but often exhibit temper tantrums

The physical appearance of these patients is usually characteristic and distinctive from that of patients with other specific and nonspecific forms of mental deficiency More than 85 per cent of phenylketonurics have blond hair and fair complexion often lighter in coloring than their parents and normal siblings The younger children usually have attractive faces Stature and head size may be average or small

The frequency and variety of skin manifestations are probably related to diminished skin pigment They range from dermatographia photosensitivity and increased

sweating to eczema which may be patchy and transient or extensive and intractable

The nervous system is frequently but variably involved Clumsiness and hyperactive reflexes are almost universally present the patients learn to walk late (two and one half to eight years) and many have a stiff jerky short stepped gait often associated with kyphotic posture or a semi rigid forward bending at the hips Stereotyped repetitive motions including head nodding and so-called "digital mannerisms" sometimes described as athetoid are common fine tremors are less common When epileptiform seizures are present their frequency tends to diminish after the age of nine or ten years Phenylketonurics of higher intelligence may have normal posture and gait and show no neurological stigmata The abnormal neurological findings are believed by some to comprise an extrapyramidal syndrome but most investigators consider them nonspecific The electroencephalogram is usually abnormal (79 per cent in Paines series) Spike and wave complexes of the petit mal variant type are frequently found even in patients without epilepsy

**Metabolic Aberration** Diagnosis is confirmed by simple qualitative chemical test of freshly voided urine To 5 ml of urine acidified with dilute sulfuric acid add a few drops of fresh 5 per cent ferric chloride solution or drop the ferric chloride reagent directly on a freshly wet diaper if phenylpyruvic acid is present a deep bluish green color appears immediately Most phenylketonurics excrete from 0.5 to 2.0 gm of phenylpyruvic acid daily However the test may not become positive until four or five weeks of age Rarely the urine of normal adults receiving high phenylalanine doses may give a positive test

Blood concentrations of phenylalanine and phenylpyruvic acid are high The urine contains a number of derivatives of these compounds phenyllactic acid phenylacetic acid phenylacetyl glutamine and  $\alpha$ -hydroxyphenylacetic acid and also tryptophane derivatives indoleacetic and indole lactic acids in amounts far beyond normal

The essential metabolic defect is an inability to convert phenylalanine to tyrosine by hydroxylation in the para position Phenylalanine can be transaminated to its keto analogue phenylpyruvate This keto acid accumulates in the blood and is partially excreted unchanged in the urine the remainder being converted enzymatically to yield phenyllactate by reduction and phenyl

acetate by oxidative decarboxylation. The phenylacetate is conjugated with glutamine to form phenylacetylglutamine.

Folling was the first to postulate a primary enzymic defect in the conversion of phenylalanine to tyrosine. Jervis and Udenfriend and associates have demonstrated the presence of a phenylalanine hydroxylase in the liver of normal human beings and its absence in the liver of phenylketonuric subjects. Mitoma and his associates and Wallace and co-workers have shown that phenylalanine hydroxylase is present in rat liver in two fractions: I, a labile fraction found only in liver; and II, a stable fraction found in many tissues including liver and brain. Their evidence suggests that the enzyme lacking in phenylpyruvic oligophrenia is similar to rat liver fraction I.

The relationship of the mental defect to the metabolic disorder is the subject of much active research. The two defects conceivably are merely concurrent, inherited in the same gene. The reports of Bickel (1954), Armstrong (1955, 1957) and others, however, indicate that in some patients the mental status seems to be favorably altered by a diet low in phenylalanine. The view that the mental retardation is secondary to the chemical aberration is a more fruitful working hypothesis, more consistent with available evidence and offers the only rational basis for therapy.

The exact manner in which central nervous system development and function are damaged, whether it is by a toxic effect of phenylalanine or of one or more of its metabolic products or by some other mechanism is not known.

The deficient ectodermal pigmentation may be the result of an inhibition of tyrosine metabolism by the excessive phenylalanine tissue levels (possibly because L-phenylalanine competes with tyrosine for the enzyme). Both high tyrosine dosages and a low phenylalanine intake with adequate tyrosine have been accompanied by increased hair pigmentation in some patients.

**Pathological Findings.** The pathological picture is variable. The following central nervous system abnormalities have been described in isolated cases: edema of the brain cord and optic nerves; gliosis; degeneration of myelin; multiple nerve tumors; and hypoplasia of the hypophysis. Other cases have shown only a diminished size of the brain. None of these findings is specific.

**Prognosis.** The prognosis for normal or even fair mental development is extremely guarded even in patients treated early in infancy and for others it is very poor. Prognosis for life in a sheltered environment is good though in the low grade patients there is the same liability to succumb to intercurrent infection that is found in other idiots.

**Treatment.** A diet low in phenylalanine corrects most or all of the abnormal chemical findings in the blood and urine. In some patients beneficial clinical effects have been described, most striking when the treatment is begun before the age of two years. These are listed by Armstrong as follows: increased attention span; increased response to environment; decreased hyperactivity of tendon reflexes; decreased spasticity and elimination of the dermatitis. A diminution in the frequency of seizures and improvement in the electroencephalogram also occurred. In some patients after several weeks of treatment there was regression; in others stabilization and in a few remarkable progression. Two children who began the corrective diet in the early months of life and were taken off at twenty-three and twenty-nine months respectively maintained IQ's of 85 after discontinuation of treatment for two years and for five months respectively. He postulates a critical age period from four months to two years during which damage to the central nervous system in phenylketonuria occurs.

The low phenylalanine diet, which is commercially available, is prepared from a protein hydrolysate from which phenylalanine is removed and to which other amino acids, minerals, and choline are added. The patient also receives supplemental vitamins, carbohydrate, and fat. Initially 5 gm of the basic mixture per kg of body weight is offered. Blood phenylalanine level is determined weekly until the normal value of 10 to 20 mg per 100 ml is reached. Low protein foods are then added to supply the minimum amount of this essential amino acid needed for growth (15 to 90 mg per kg of body weight).

## HEPATOLENTICULAR DEGENERATION

(Wilson's Disease)

The disorder known as Wilson's disease is a familial coarsely nodular cirrhosis of the liver which in some patients is associated with progressive damage to the nervous system resulting in the appearance of tremor and rigidity. There are two chief types of the disease. One is a more rapidly progressive disorder appearing in late childhood or early adolescence with rigid posture and pseudobulbar symptoms in addition to tremor; the "progressive lenticular degeneration of Wilson." The other is a slowly progressive disorder characterized chiefly by tremor and titubation appearing in the third or fourth decade and running a course of many years (pseudo sclerosis). Intermediate mixed types are more common than these extremes.

**Pathology** Some degree of coarsely nodular cirrhosis of the liver is found in all cases with variable extent of recent degeneration of some lobules of the type seen in acute yellow atrophy. Regenerative activity is intense in a few cases, portal obstruction and its effects are obvious but in most this is minimal.

The nervous system may appear normal to the naked eye except for some shrinkage of the basal ganglia and brownish pigmentation of the putamen (the outer segment of the lenticular nucleus). Throughout the central nervous system but most evident in the cerebral cortex, basal ganglia, thalamus and dentate nuclei, there is a great increase in number of the large astrocyte nuclei. These astrocytes are sometimes present in lobulated or even giant cell forms with light brown pigment in the cytoplasm. In the more rapidly progressive forms of the disease, edematous areas in the glia appear in the frontal cortex, lenticular and dentate nuclei. When intense this process leads to the appearance of cavitation in these situations as originally described by Wilson.

The pigmentation of the cornea is present in fine granules in Descemet's membrane and has been shown chemically and spectroscopically to contain chiefly copper with traces of zinc and other metals. The pigment in the cerebral glia, the liver and occasionally the skin appears to be identical. The copper content of the liver and of the brain, especially the basal ganglia, is greatly increased. There is no evident renal lesion and in distinction from the Fanconi syndrome the first collecting tubule is reported to be of normal length.

**Symptoms and Signs** In some families the cirrhosis is a prominent feature and episodes of ascites or hematemesis are frequent. More commonly symptoms of liver damage are entirely absent though cirrhosis is invariably present in some degree. Jaundice is not a symptom and tests of liver function are usually not helpful unless there has been clinical evidence of a recent hepatic embarrassment. Cephalin and thymol flocculation have been the most frequently positive liver function tests. Liver biopsy with histochemical staining of copper by rubeanic acid is the most specific test.

The disease is characterized by a consistently high output of amino acids and copper in the urine so that up to 10 gm of amino acids and 1000 micrograms of copper may be excreted in twenty-four hours. The biliary excretion of copper is normal. There is an overabsorption of copper from the alimentary tract and an increased deposition of copper in all organs.  $\text{Cu}^{64}$  studies indicate that the urinary copper is derived from the copper released from tissues rather than that directly absorbed. In the plasma there is a reduction of the blue copper protein caeruloplasmin and the related oxidase activity. The total copper level is little altered for though this indirect fraction is low the direct copper fraction is abnormally high. Caeruloplasmin could have only a minor function in producing an overabsorption of copper. The overabsorption may be a result of an increased affinity for copper that the tissue proteins intrinsically possess biochemically demonstrable in liver and cornea in this disease.

The patient may succumb to the effects of hepatic cirrhosis without developing neurological symptoms other than terminal coma. More commonly tremor and dystonia with pseudobulbar phenomena in the form of dysarthria and fixed smiling expression appear. In the more rapidly progressive forms of the disease dystonic attitudes such

as overpronated postures of the arms choreic movements inversion of the feet open mouthed fixed smile with difficulty in mental concentration first appear between the ages of fourteen and eighteen the earliest age reported being four years In a few months the limbs may become greatly distorted by dystonic rigidity and slow rhythmical tremors appear leading to a termination in one to three years If the onset occurs after the age of eighteen to twenty the course is slower and the characteristic tremor is prominent When the neurological disorder appears after the age of twenty five tremor and dysarthria may be the only signs associated with slow mental deterioration The tremor is a flapping of the hands at the wrist as in waving good bye and is present when the hands are outstretched It is then accompanied by alternating adduction abduction at the shoulder Titubation of the head and dysarthria are common indicating that the essential tremor is cerebellar in type In more progressive types of the disease a plastic rigidity of the limbs and set expression of the face appear and in time the pill rolling tremor of the fingers of parkinsonian type is added The lower limbs then also become affected

**Pigmentation of the outer margin of the cornea in the form of a smoky brownish ring (the Kayser Fleischer ring) seen best by oblique lighting is absolutely characteristic of this disease It is constant in the more chronic forms but may be absent in the more rapidly progressive forms of the disease**

**Treatment** Treatment by diets designed to favor liver function has not had any lasting effect on the neurological symptoms Improvement sometimes striking in degree has followed the periodic mobilization of copper deposits by BAL (2,3 dimercapto propanol) 1.0 to 1.5 ml of 10 per cent solution in peanut oil intramuscularly once weekly for an indefinite period Such improvement has been maintained for eight years in one patient and between five and seven years in five others These were all cases of the pseudosclerotic type who ultimately succumb from progressive portal obstruction after many years with or without chelation The dystonic form of the disease also usually shows improvement with chelation but within a period of one to three years develops a periodic jacksonian convulsive disorder that does not respond to chelation Each such attack brings further dystonia without fresh hepatic damage and ultimately death in coma The

cause of this type of relapse which can also occur without specific treatment and without fresh liver damage is unknown Other chelating agents such as versene and penicillamine have received limited trials Alternation of high and low protein diet also increases copper excretion Potassium sulfide 20 mg in enteric coated capsules is given in one capsule with each meal to render copper in the diet insoluble No satisfactory way of eliminating copper from the diet has been found General anesthetics and barbiturates are very poorly tolerated but cyclopropane ether has been successfully used in five reported cases

## FAMILIAL PERIODIC PARALYSIS

This syndrome is characterized by periodic attacks of flaccid paralysis usually involving the muscles of all four extremities and the trunk but occasionally affecting only the arms or legs The condition is hereditary has its onset during the first or second decade of life and persists for a number of years The attacks usually develop during the night and if untreated last for a few hours to a few days Attacks may recur daily or may be separated by intervals of a year or more The tendon reflexes are abolished the muscles can be

completely refractory to all types of stimulation and during particularly severe attacks cardiac and respiratory involvement can occur. Sensation and mental faculties are not impaired. During periods between attacks the findings are normal.

**Pathological Physiology.** The attacks of paralysis are typically associated with hypokalemia and in susceptible subjects may be precipitated by measures that decrease the concentration of potassium in the serum.  $\blacksquare$ g the ingestion of  $\blacksquare$  large amount of carbohydrate the concomitant administration of glucose and insulin or the administration of a "salt retaining" steroid or of epinephrine. However there is no consistent correlation between the onset and intensity of attacks and the degree of depression of serum potassium levels. The ratio between potassium in intracellular and extracellular water is about 30:1 consequently quite large variations in intracellular potassium may occur without detectable change in serum levels. There is evidence suggesting that during an attack potassium is shifted to an intracellular site and that the attack is not characterized by urinary loss of potassium or sodium. On the other hand Conn has shown that attacks are preceded by the retention of sodium with concomitant fall in serum potassium and a sharp rise in urinary aldosterone. Recovery is associated with changes in the opposite direction. Measures known to induce attacks in the presence of a normal or high intake of sodium may fail to do so when sodium intake is sharply curtailed. Conn believes the primary disturbance may be an increase in intracellular sodium and that sudden alterations in potassium metabolism may be contributory to the induction or alleviation of paralysis.

**Differential Diagnosis.** Familial periodic paralysis must be distinguished from other disorders in which muscle weakness is associated with detectable disturbances in potassium metabolism. These include primary aldosteronism, Cushing's syndrome, potassium losing nephropathies (e.g. renal tubular acidosis), excessive administration of diuretics including chlorothiazide and mercurials, diarrheal disorders including the excessive use of cathartics with associated loss of potassium and steroid therapy. In all of these disturbances as well as in familial periodic paralysis the electrocardiogram may show the changes characteristic of hypokalemia.

Muscular weakness and paralysis may be associated with hyperkalemia occurring under different conditions e.g. in ad-

vanced renal disease in sodium depletion and in a hereditary syndrome designated *adynamia episodica hereditaria*. This latter disorder resembles familial periodic paralysis in many respects and could be confused with it. However all these types of hyperkalemia may be associated with paresthesias and show increased levels of serum potassium as well as electrocardiographic changes typical of hyperkalemia. Administration of potassium does not improve symptoms and indeed may have pronounced paralytic effect. It should be emphasized that in all of these syndromes definitive diagnosis may require more than a single observation of the serum potassium or the electrocardiogram.

**Treatment, Prevention and Prognosis.** Attacks may be terminated in a few hours by the oral administration of 5 to 15 gm of potassium chloride. For prevention of frequently recurring attacks restriction of dietary sodium is recommended; the daily administration of 10 to 30 gm of potassium chloride is often of great value.

The prognosis for life is usually excellent and attacks often decrease in frequency and intensity over the years. Very occasionally patients succumb from respiratory failure.

#### PORPHYRIA

**Definition and Classification.** Porphyrin may be defined as "constitutional fault or inborn error" in porphyrin metabolism. It is probably best to limit the term to cases in which uroporphyrin and/or porphobilinogen are excreted in great excess since this characterizes the constitutional abnormality. Thus used the term porphyria em-

as overpronated postures of the arms choreic movements inversion of the feet open mouthed fixed smile with difficulty in mental concentration first appear between the ages of fourteen and eighteen the earliest age reported being four years In a few months the limbs may become greatly distorted by dystonic rigidity and slow rhythmic tremors appear leading to a termination in one to three years If the onset occurs after the age of eighteen to twenty the course is slower and the characteristic tremor is prominent When the neurological disorder appears after the age of twenty five tremor and dysarthria may be the only signs associated with slow mental deterioration The tremor is a flapping of the hands at the wrist as in waving good bye and is present when the hands are outstretched It is then accompanied by alternating adduction abduction at the shoulder Titubation of the head and dysarthria are common indicating that the essential tremor is cerebellar in type In more progressive types of the disease a plastic rigidity of the limbs and set expression of the face appear and in time the pill rolling tremor of the fingers of parkinsonian type is added The lower limbs then also become affected

### FAMILIAL PERIODIC PARALYSIS

This syndrome is characterized by periodic attacks of flaccid paralysis usually involving the muscles of all four extremities and the trunk but occasionally affecting only the arms or legs The condition is hereditary has its onset during the first or second decade of life and persists for a number of years The attacks usually develop during the night and if untreated last for a few hours to a few days Attacks may recur daily or may be separated by intervals of a year or more The tendon reflexes are abolished the muscles can be

the urine in the erythropoietic and the pure cutanea tarda types and conversely is prominent in the intermittent acute type in which skin lesions are not a feature. In the photosensitive types uroporphyrin is readily demonstrable in the circulating blood whereas this is exceptional in the intermittent acute types.

Although the urine in acute porphyria contains large amounts of porphobilinogen and its immediate precursor delta amino levulinic acid there is no evidence that either of these compounds is directly responsible for the abdominal or nervous manifestations of the disease. The mechanism of their production remains unexplained.

In the erythropoietic (congenital) form the teeth may be red or reddish brown (erythrodontia). According to Garrod this is an evidence that the excessive formation of uroporphyrin began during fetal life. At necropsy the bones are red in varying degree owing to deposition of uroporphyrin. The bone marrow is usually hyperplastic and normoblastic often in association with splenomegaly and hemolytic anemia.

In this form of the disease many of the normoblasts of the bone marrow contain large amounts of porphyrin. This has been shown to be a mixture of uro copro and protoporphyrin. The nuclei are especially rich in porphyrin content as shown by fluorescence microscopy. Circulating erythrocytes also contain marked excesses of uro and coproporphyrin and the spleen is rich in these substances probably because of the excessive destruction of erythrocytes and storage of the porphyrin which they contained. Lesser amounts are found in the liver. In certain instances splenectomy is followed by a marked and sustained reduction of porphyrin formation in the bone marrow. This is believed due to a reduced erythropoiesis dependent upon a reduced rate of blood destruction as a consequence of the splenectomy.

Evidence of liver injury or liver disease is frequently encountered in the hepatic types. Clinical evidences of hepatic disturbances are discussed in the following section. Liver biopsy or examination of the liver at necropsy may reveal varying degrees of fatty liver, cirrhosis or liver cell injury. Fluorescence microscopy in the cutanea tarda type reveals large amounts of preformed uroporphyrin. In the intermittent acute type there is relatively little fluorescence but porphobilinogen is readily demonstrated. In the combined or mixed type varying transitions are observed and

there is evidence that the ratio of non fluorescing precursor to porphyrin varies from time to time. In the hepatic forms of porphyria the bone marrow porphyrin content is normal and porphobilinogen is not demonstrable.

Inconstant and nonspecific changes have been observed in the nervous system from time to time in fatal cases of the intermittent acute type. Microscopic changes indicative of nerve cell injury have been described in both the central nervous system and the sympathetic ganglia. Recent observations point strongly toward an important role of the sympathetic nervous system in relation to certain of the manifestations of the intermittent acute type notably abdominal pain and hypertension. Tetraethylammonium chloride often relieves the pain and lowers the blood pressure. In one instance in which there had been abdominal pain almost daily for a long period complete relief has been afforded by splanchnicectomy for at least two years after the procedure was carried out.

**Symptoms and Signs** In the photosensitive types the earliest symptom is most often the appearance of small bullae or vesicles on the face or hands after exposure to sunlight with production of the syndrome of hydroa aestivale seu vaccini forme. As will be emphasized later porphyria is by no means the only cause of this syndrome.

In some instances of the hepatic cutanea tarda type the skin lesions may be urticarial or eczematoid. These patients often exhibit in addition an increased brownish pigmentation of the skin. It should be noted that brownish pigmentation of an Addisonian type may also occur in cases of intermittent acute porphyria in the absence of any photosensitivity. Brunsting and others have emphasized that in the cutanea tarda type vesicles are often caused by heat and trauma as well as by light. As Brunsting has pointed out the face in this type at times presents a peculiar violaceous hue.

Varying degrees of hirsutism are often observed especially in the erythropoietic form of the disease at times in the hepatic cutanea tarda rarely in the intermittent acute form. The basis of this is unknown.

In contrast to the paucity of visceral manifestations in the pure photosensitive type the variations in symptomatology and physical findings in the intermittent acute and combined hepatic types have undoubtedly been responsible in many instances

braces two fundamentally distinct groups (1) erythropoietic (2) hepatic. The former is synonymous with what Gunther described as porphyria congenita. The latter includes (a) the intermittent acute form (b) the cutanea tarda type (Gunther's "chronic" porphyria) (c) the combined or "mixed" type (d) latent porphyria. There is reason to believe that there are at least two genetic variants of acute porphyria. According to Waldenström the form observed in Sweden exhibits no relationship to the cutanea tarda type while in the families studied by Dean in South Africa all of the types of hepatic porphyria are represented. Certain differences in the porphobilinogen and porphyrin excretion during remission and in latent cases have also been noted and will be mentioned again.

**Incidence.** The erythropoietic (congenital) form of the disease is distinctly rare. Many of the cases described in the literature as congenital porphyria are undoubtedly of the hepatic cutanea tarda type differing fundamentally from the erythropoietic disease. The hepatic intermittent acute type is the most common form of porphyria. It has often been overlooked because of its close mimicry of various other pathological states. Of 203 well documented cases of all types collected by the author only 6 were erythropoietic; the remainder were hepatic of which 119 were of the intermittent acute type, 34 were of the cutanea tarda type, 11 were combined or mixed and 33 were latent.

Although it has been believed that striking differences in sex incidence exist between the congenital and acute types of porphyria, recent studies based on the above mentioned fundamental classification fail to reveal any significant sex difference in the erythropoietic type but the hepatic intermittent acute form is somewhat more common in females. The ratio in 119 cases was about 1 : 1.0. The cutanea tarda form is distinctly more frequent in males; a ratio of 26 to 8 being noted in 34 cases. The age at onset of manifestations is much earlier in the erythropoietic disease usually in infancy or early childhood, the condition in some instances being evident at birth. In the hepatic forms symptoms are rarely noted before puberty, the age at onset more often being in the third or later decades.

**Etiology.** Erythropoietic porphyria is an "inborn error" due to a non sex-linked recessive gene. Hepatic porphyria in its various forms is also familial, a non sex-linked dominant genetic trait.

Gunther and others used the term *toxic acute porphyria* to imply that some cases were acquired on the basis of chemical poisoning. There can be no doubt that acute attacks are often precipitated by chemicals in the hepatic intermittent acute form of the disease. Sulfonal, Trional, barbiturates and less frequently a variety of other chemicals, even including alcohol, have been implicated. Waldenström and others have clearly demonstrated that barbiturates may precipitate attacks in individuals having latent porphyria previously free of symptoms. Such latent cases were identified because other members of the patients' families had manifest disease. The exact mechanism by which chemicals precipitate attacks is unknown. This variety of porphyria is to be distinguished sharply from the ordinary symptomatic or secondary coproporphyrinuria. Coproporphyrin is normally present in urine and feces and is increased in a variety of pathological states including lead and other heavy metal poisoning, chemical toxicity (especially benzene ring compounds), hepatic disease, certain afflictions of the nervous system and in some of the anemias. The secondary porphyrinurias constitute a separate topic quite distinct from that of porphyria and will be considered here only from the standpoint of differential diagnosis.

On occasion considerable excesses of porphobilinogen and/or uroporphyrin are found in the urine in cases of severe diseases such as carcinomatosis, Hodgkin's disease, systemic infections, nervous system disease or advanced liver disease in which the ordinary clinical manifestations of porphyria are lacking. The reason for the increased excretion of these substances in such cases is not clear. The possibility has been considered that they represent latent porphyria in association with another disease such as mentioned.

**Morbid Anatomy and Pathological Physiology.** In the photosensitive types the principal lesions are those due to light sensitivity of the exposed areas of skin, viz. the face, ears and hands.

It has thus far been impossible to reproduce skin lesions by artificial light of the wave length believed optimal on the basis of the uroporphyrin absorption spectrum. Nevertheless, uroporphyrin I is a strongly photosensitizing substance and it is reasonable to believe that it is responsible for the skin lesions, perhaps on the basis of repeated or chronic sunlight exposure. Porphobilinogen is entirely lacking from

tion to being a porphyrin precursor gives rise to porphobilin a dark brown non porphyrin pigment of unknown chemical structure. Probably because of its content of this pigment the urine of the intermittent acute type of porphyria is darker with more brown and less red color than that of the pure photosensitive types. Porphyrin urine usually contains an excessive amount of coproporphyrin. The porphyrin and pigment content of the urine is much more complex in the intermittent acute than in the photosensitive type of the disease.

**Differential Diagnosis** The possibility of porphyria should be borne in mind in the presence of any obscure nervous disturbance especially unexplained peripheral neuritis flaccid paralyzes of extremities bulbar palsy and hysteria. It should also be searched for in any instance of abdominal pain which is otherwise unexplained. Among other conditions the disease has been confused in the past with gallstone colic renal colic appendicitis bowel obstruction and lead poisoning. In the last the urine regularly contains a marked increase of coproporphyrin but rarely any marked excess of porphobilinogen or uroporphyrin nor is the amount of coproporphyrin sufficient to color the urine red. In gallstone colic the urine Ehrlich reaction may be positive because of excessive urobilinogen. Confusion of porphyria with renal colic has usually been due to the belief based on superficial examination that the red urine was due to blood and the pain due to ureteral calculus. Careful examination of the urine will obviate this mistake. The lack of rebound tenderness and muscle spasm together with the urinary findings serves to distinguish porphyria from appendicitis. The leukocyte count is usually normal but in exceptional cases may be considerably elevated. The roentgenographic findings aid in excluding bowel obstructions the characteristic layering of the small bowel not being observed. Areas of marked alternating spasm and distention of the large bowel are rather common especially of the transverse colon and splenic flexure. In rare instances volvulus and gangrene of the cecum or strangulation of small bowel has been a sequel of the attack.

Hypertension is noted in some cases and it is of interest that lumen attenuation of retinal arteries of spastic type may be seen in such instances. During the acute attack the hypertension may be associated with oliguria and these manifestations coupled with the dark urine may give rise to a

superficial resemblance to acute glomerulonephritis. If the attack subsides and the disease becomes quiescent or latent the blood pressure returns to normal and retinal vascular abnormalities may disappear entirely. Electrocardiographic changes are observed in some cases.

At times the persistent tachycardia and muscle weakness may be suggestive of hyperthyroidism. In other cases weakness and pigmentation give rise to consideration of Addison's disease. The pigmentation is present in but a minority of cases. It is usually rather patchy in character in some cases associated with intervening vitiligo. The nature of the pigment has not been determined. In one case seen by the writer the patient at an earlier age had had an appendectomy which failed to relieve the attacks of abdominal pain for which it was done several years later she underwent a thyroidectomy because of tachycardia weakness and nervousness later still in another hospital she received salt and adrenal extract treatment for supposed Addison's disease on the basis of weakness and mild pigmentation of the skin. Subsequently this patient had severe abdominal pain and paralyzes of all four extremities from which however she recovered completely. Fourteen years later she had had no recurrence of symptoms and at this time the urine and fecal porphyrins were entirely normal.

Occasional cases are observed in which chronic constipation and long standing abdominal pain are prominent and in which the urine contains a several fold increase of coproporphyrin but neither porphobilinogen nor increase of uroporphyrin. A satisfactory classification of these cases is impossible at the present time but it does not appear that they should be included in the category of true porphyria. As a matter of fact they will not be recognized as involving any disturbance of porphyrin metabolism unless a quantitative study of coproporphyrin excretion is made.

Many cases of "hydroa aestivale seu vacuiniforme" bear no relation to porphyria although the skin lesions may be indistinguishable. In some of these it is evident that ordinary window glass prevents the photosensitivity since it absorbs the exciting light (below 3000 Å). In the photosensitive types of porphyria the wavelength of the light most important in inducing skin lesions is probably in the neighborhood of 4000 Å with the result that window glass is not protective.

**Prognosis** In the erythropoietic photo

for confusion in diagnosis. For the most part the symptoms are either nervous or abdominal in character, not infrequently both are present in the same case. In the combined type photosensitive skin lesions are added in varying degrees. They may precede, coexist with or follow the nervous and/or abdominal manifestations.

The *nervous manifestations* may be referable to any part of the nervous system: central, peripheral or autonomic. The more acute attacks of the disease may be preceded for many years by undue nervousness, neurasthenia or mild hysteria. More severe psychic abnormalities ranging from marked hysterical behavior or outspoken psychoses of manic depressive or Korsakow type to delirium or coma have been described. Epileptiform convulsions or even typical grand mal seizures may occur. Various cranial nerve involvements have been reported with resulting manifestations which include optic atrophy, eye muscle palsies, dysphagia and persistent tachycardia. Hoarseness due to vocal cord weakness or outspoken paralyses of the skeletal muscles are often noted. These are usually patchy, at least at the outset, although in many instances all four extremities become involved to the extent of a rather complete flaccid quadriplegia with marked wrist and foot drop. The disease has been confused with Landry's ascending paralysis but as Waldenström has emphasized the paralysis of porphyria is usually not of the ascending type or symmetrical in development. In some cases but one or two extremities are involved and there may be nothing more than distinct weakness. The deep reflexes are hypoactive or entirely absent. At times there is hyperactivity of the Achilles reflexes or even outspoken clonus with absence of knee jerks. In developing paralyses, muscle atrophy and contractures commonly ensue, although the extent to which recovery may occur between attacks is often more surprising. The appearance of weakness of the extremities is often preceded and accompanied by persistent severe pain similar to that observed in some cases of diabetic neuritis. The pain is stubborn and difficult to control and is often worse during the night. The *abdominal pain* is also severe and usually colicky. It may be generalized or localized to any part of the abdomen or loins. Abdominal distention may be present but the lack of muscle spasm and rebound tenderness is usually in contrast to the severity of the pain. Marked constipation is the rule although exceptional cases exhibit diarrhea.

**Diagnosis.** The examination of the urine for porphobilinogen and uroporphyrin is paramount. Porphobilinogen is the name which Waldenström gave to the colorless precursor of the two principal pigments of porphyria in urine. It has recently been shown to be a monopyrrole while the porphyrins are tetrapyrrolic. As already mentioned this chromogen does not occur in the urine of the erythropoietic or hepatic cutaneous tarda type and is observed in cases of the combined type only in association with abdominal or nervous manifestations.

The photosensitive types are characterized by the presence of large amounts of uroporphyrin with the result that the urine is red and at once attracts attention. Spectroscopic examination readily permits identification of the uroporphyrin. Interestingly enough the small amounts of uroporphyrin excreted in the intermittent acute cases are mainly zinc complex while in the erythropoietic type it is present chiefly at least as the free porphyrin. The significance of the zinc complex is not clear. It has been observed however in cases of "mixed" type with photosensitivity but during complete remission of abdominal or nervous symptoms, thus a causal relationship with the latter appears unlikely.

The urines from cases of the intermittent acute type need not be abnormally colored even during the acute attack although in most cases the patient will have noticed a darkening of the urine at the outset. Porphobilinogen is usually present in large amounts at this time. If the fresh urine is normal in color the diagnosis may be overlooked unless the chromogen is sought for. If the urine is allowed to stand in the light to bring about the characteristic darkening of the uroporphyrin (metal complex) spectrum is then readily detected. The porphobilinogen is demonstrable in fresh urine by means of the Ehrlich aldehyde test. The resulting red compound is chloroform insoluble, a fact which serves to distinguish it from urobilinogen aldehyde. During relapse of acute porphyria the porphobilinogen aldehyde reaction is invariably strong and unmistakable. If the reaction is a faint pink, questionable or absent it is quite unlikely that symptoms are on the basis of porphyria. In remission porphobilinogen may disappear from the urine quite completely as is characteristic of the South African cases or it may persist undiminished as is often true in the Swedish cases. Wide variations are evident in this regard in cases observed in the United States. Porphobilinogen in addi-

some cases Patients with latent porphyria should be given a written statement concerning the diagnosis and danger of barbiturates and other chemicals to carry on their person at all times

## Gout and Gouty Arthritis

Gout is a disease of unknown origin characterized by (1) acute recurrent arthritis sometimes chronic arthritis later (2) slow accumulation of sodium biurate manifested by hyperuricemia and tophi and (3) secondary lesions affecting the kidneys "Acute gout" is a misnomer gout *per se* is always chronic

Gout is seen commonly if kept in mind It is not the disease but an awareness thereof which "disappears" from time to time

**Predisposing Factors** About 95 per cent of patients are males The reported incidence of active familial gout has been low (7 to 18 per cent) among American patients much higher (22 to 80 per cent) among British patients Heredity is more apparent among juveniles than adults with gout Gout occurs mostly in temperate zones It is common in England and France less common in North America Scandinavia Poland and Russia and almost unknown in the Orient and tropics Negroes are rarely affected Habitual or episodic excesses of food and drink probably do not predispose to gout *per se* but they may

incite acute gouty arthritis They are provocative not predisposing factors Gout can occur in vegetarians and teetotalers Although the incidence of gout is higher among patients with blood dyscrasias such as myeloid metaplasia polycythemia and leukemia ("secondary gout") most patients so afflicted do not develop acute gouty arthritis even if hyperuricemia is present

**Morbid Anatomy** In gout urates tend to deposit in cartilage (ears joints rarely the nose) epiphyseal bone other articular structures and kidneys rarely elsewhere Crystalline urates produce local necrosis and (unless tissue is avascular) an ensuing foreign body reaction with proliferation of fibrous tissue the "gouty granuloma" Cartilaginous degeneration synovial proliferation destruction of subchondral bone ("destructive arthritis") proliferation of marginal bone ("hypertrophic arthritis") often synovial pannus and sometimes fibrous or bony ankylosis may slowly develop In the kidneys one finds gross and microscopic urate deposits in tubules medulla and interstitial tissues linear streaks in the pyramids and uratic gravel or calculi Secondary destructive and inflammatory reactions develop Thus the "gouty kidney" may appear as focal pyelonephritis nephrosclerosis or chronic glomerular nephritis (fibrosis hyalinization)

Nonspecific lesions such as atherosclerosis of the blood vessels of the heart and brain occur in gouty subjects but it is not clear whether the incidence is higher than in nongouty persons of similar age

**Evolution of Symptoms Clinical Stages of Gout** The chief features (arthritis hyperuricemia tophi late renal complications) are the outward signs of a fundamental disturbance of which little is known This disturbance ("gouty diathesis" gout *per se*) is in operation long before it first manifests itself as clinical gout The successive phases of the development of the disorder may be designated the "carrier stage" the stage of acute recurrent arthritis with complete remissions and the stage of chronic gouty arthritis It should be emphasized that the terms gout and gouty arthritis are not synonymous the latter is merely the dominant symptom of gout

**The Carrier Stage** While "hereditary hyperuricemia" is genetically transmitted and the trait therefore is present in the newborn it is not detectable for a prolonged period In the male this latent stage usually lasts until puberty (when asymptomatic hyperuricemia ordinarily makes its appearance) in the female not until later

sensitive type the outlook for life is relatively good the disease having a long chronic course and death being due to intercurrent affections of one kind or another. In some instances however severe anemia hemolytic in character is the most important governing factor in prognosis. In the intermittent acute type the mortality is relatively high especially in cases with nervous system manifestations. In the past a figure of 80 per cent within five years from the time of the first attack has generally been accepted but our own experience indicates that the prognosis is by no means as poor as this would indicate. In the authors' material many patients are alive and in relatively good condition or asymptomatic more than five years from the time of the first symptoms of the disease. In Dean's large experience in South Africa there have been no deaths for a number of years. Dean believes that with meticulous care very few patients will die. In those cases in which only abdominal symptoms are present the outlook is distinctly better although these cases too may develop nervous system involvement at any time.

**Treatment.** From the standpoint of photosensitivity this is purely preventive consisting in protection from the light. As stated ordinary window glass does not filter out the exciting light. There is some evidence that vitamin B<sub>1</sub> is beneficial in reducing or eliminating photosensitivity in the hepatic cutanea tarda group but the writer's own experience with it has been indecisive.

Splenectomy is of value in at least some cases of the erythropoietic type with splenomegaly and hemolytic anemia. In one of our cases splenectomy has been followed by a complete symptomatic remission of the disease for a period of over eight years. The anemia and photosensitivity have disappeared and the porphyrin excretion though still abnormal has decreased remarkably.

Various methods of treatment have been advocated for the intermittent acute type but until recently all have been inconsistent or doubtful in their effectiveness. The experience with chlorpromazine in the past three years indicates that it is much more valuable in the treatment of acute porphyria than any previous agent or method. The great majority of patients obtain prompt relief of pain and nervous manifestations although established paralyses are unaffected. Following the use of this drug in adequate dosage (up to 100

mg four times in twenty four hours) a remission of the disease has usually taken place. At the same time it is clear that there is no direct effect on the disturbance of porphyrin metabolism as the excretion of porphobilinogen and porphyrins is unaltered by the drug and declines slowly only after the disappearance of symptoms. It appears that chlorpromazine by allaying pain and nervousness interrupts a vicious cycle and permits the patient to go into remission. This implies the presence of an important psychobiological factor which can scarcely be doubted on the basis of many observations.

Other methods regarded as inferior to of investigators have stated that the administration of crude liver extract has relieved chlorpromazine nevertheless deserve brief mention. Calcium given intravenously has been reported to be beneficial. A number suited in improvement. The author's experience with both of these methods has been disappointing. Demerol 50 to 100 mg given hypodermically has been of value in allaying pain although its effect has seldom lasted more than 4 hours. In some instances it was clearly more effective than morphine probably because of its antispasmodic as well as analgesic effect.

Tetraethylammonium chloride has been of definite value in reducing or eliminating pain. One injection of 200 to 250 mg intravenously or 500 to 1000 mg of the chloride intramuscularly has provided complete relief for as long as twelve hours in some cases. It is well to commence with a small dose as some cases are unduly sensitive and develop untoward hypotension. In some cases a beneficial effect is entirely lacking. Hexamethonium has been used in small amounts in two cases but in both was followed by a profound drop in blood pressure again indicating that there may be an unusual sensitivity in this disease.

In a number of instances prompt remission has occurred following brief ACTH therapy. In others no definite beneficial effect has been observed and in a few it has been thought that the effect was adverse actually hastening the patient's demise. Present experience indicates that a brief trial of ACTH is warranted. If no definite benefit has been observed within a four-day period it probably should not be continued.

Barbiturates should not be used since there is definite evidence that they may precipitate or intensify the attacks. There is evidence also that other chemicals including alcohol are precipitating factors in

such not regarded merely as a worsening of chronic uratic gouty arthritis

Patients whose first attack develops in middle or later life may never develop notable tophaceous deposits chronic gouty arthritis or significant renal involvement

**Acute Gouty Arthritis Typical Attack**  
Some patients recognize prodromes irritability melancholia nocturia polyuria vague muscular symptoms nausea dyspepsia or sometimes euphoria and a ravenous appetite Attacks begin any time day or night Those beginning at night if severe may awaken the patient in the early morning hours if mild they do not awaken the patient but are noted first when on awakening he puts his foot to the floor

In gout there is a gradient of articular vulnerability whereby distal joints—feet ankles hands wrists—are most commonly affected knees and elbows are less vulnerable Shoulders and hips are rarely affected clinically except in severe or late gout Although the spine may acquire urate deposits acute or chronic gouty spondylitis is very rare Olecranon bursitis and tendinitis especially of Achilles tendon often occur

Attacks generally develop rapidly sometimes slowly Maximal disability may appear within twelve to thirty six hours Pain may be mild or moderate but is often severe—so excruciating that the weight of bedclothes or vibration of the bed is unbearable It is not always worse at night

The affected part is swollen and tender (Fig 63) often exquisitely so The skin may be bright or deep red sometimes dusky In

inflammatory pitting edema may develop As swelling subsides there may be itching and desquamation Spontaneous recovery is sometimes slow but often rapid—within a few or several days In articular stage 1 clinical recovery is complete whether or not there are roentgenographic residues—a point of diagnostic importance "A person subject to gout has won the race at the Olympic games during the interval of the disease" (Aretaeus)

**Predisposing and Provocative Factors**  
**PREDISPOSING FACTORS** Among men over thirty five years of age gouty arthritis is the commonest form of acute arthritis It should always be suspected when acute trauma is excluded Attacks come any time commonly in spring and fall Habitual (in contrast with acute) excesses of rich or purine rich food and drink may condition patients to frequent attacks

**PRECIPITATING FACTORS** There are many provocatives of acute gouty arthritis trauma acute indiscretions as to food or alcoholic drinks psychic upsets chilling and hemorrhage certain therapeutic agents or procedures—liver extract mercurial diuretics ergotamine tartrate testosterone propionate roentgen therapy probenecid (Benemid) thiamine chloride (vitamin B<sub>1</sub>) dehydrocholic acid (Decholin) high fat or ketogenic diets penicillin sulfathiazole transfusion purging bleeding possibly injections of pollen extract Contact with provocatives must be sought patients rarely recognize them

Attacks may be precipitated by minor trauma as from excessive walking long

FIG 63 Acute gouty arthritis of great toe

FIG 62 The basic pattern of gout and gouty arthritis (untreated) (P S Hench J Lab & Clin Med Vol 22)

often not until the menopause. The serum uric acid level may be only intermittently increased in the early phases. Affected subjects usually are entirely symptomless until the first attack of acute gouty arthritis appears which ordinarily does not occur for many years and indeed may not occur at all. In some instances however there may be antecedent attacks of renal colic due to urate stones or gravel as an indication of the underlying metabolic disorder. Very rarely in 2 per cent or less of cases detectable subcutaneous urate deposits (tophi) appear before any acute seizure.

**Stage of Acute Recurrent Arthritis With Complete Remissions.** The first attack of acute arthritis usually occurs suddenly lasts a few days or weeks then disappears completely. It affects a great toe or with almost equal frequency ankle instep or knee. Sooner or later (a few months a year or longer) there is another attack perhaps more severe or longer it also disappears completely. Then attacks commonly increase in severity and frequency coming semiannually or oftener.

Early attacks are generally monarticular afebrile and short (articular phase 1 Fig 62). Later attacks are often polyarticular longer and perhaps febrile (articular phase 2). Permanent roentgenologic changes may slowly develop despite which in this stage of the disease joints recover full symptomless function.

During articular phases 1 and 2 attacks of acute olecranon bursitis may develop also with complete remissions. In early attacks thereof there may be no palpable bursal tophi. Acute bursitis may develop with or without acute arthritis.

**Stage of Chronic Gouty Arthritis.** From five to forty (average twelve) years after

the first attack an important change may become apparent: the onset of chronic gouty arthritis the second form of articular gout. Sometimes when first discovered it appears to be the residue of an acute attack a joint no longer recovers completely. But it may develop insidiously without immediate reference to any previous attack.

Chronically affected joints may be subject to superimposed acute attacks (phase 3 Fig 62). But sometimes acute attacks (or "exacerbations") cease to recur (phase 4). Chronic gouty arthritis usually becomes polyarticular: hands and feet may be misshapen by tophaceous deposits and deformities. Tophi are usually present on the ears. By now olecranon or prepatellar bursal walls may be chronically thickened from urate deposits and the tissue reactions thereto. Chronic tophaceous "bursitis" may be painless or mildly painful a process apparently independent of the acute attacks of bursitis which may or may not continue to recur.

Thus the pattern of classic gouty arthritis can be divided clinically into two stages comprising four phases (Fig 62). Although the stage of chronic gouty arthritis (or chronic bursitis) almost always appears after that of acute recurrent gouty arthritis these two clinical stages are not completely or necessarily interdependent. Indeed from the etiological or pathogenetic standpoint acute gouty arthritis and chronic gouty arthritis may be independent unrelated developments. The pattern of acute recurrent gouty arthritis ordinarily continues basically unchanged after the development of chronic gouty arthritis. If an acute attack is suddenly superimposed upon a joint which is the seat of chronic gouty arthritis this should be recognized and treated as

of the disease and increased values in 80 to 85 per cent (Hench Mason). The serum urate levels of normal and gouty patients fluctuate considerably from day to day. In some gouty patients they fluctuate above and below the upper limit of normal at least early in the disease in others concentrations remain above normal but fluctuate without regard to attacks or to the use of nonuricosuric agents such as colchicine. Urinary concentrations of urate (during periods without treatment) may fluctuate considerably even on a fixed diet.

Visible or palpable *subcutaneous tophi* may develop at any stage occurring in about 30 to 50 per cent of cases. They are rare in the prearthritic stage uncommon in articular phase 1 more frequent in phase 2 and almost always present in phases 3 and 4 when they may be multiple and ulcerating (Fig 64). They occur on the ears (Fig 65) and about olecranon bursae and peripheral joints. A tophus is not a proved tophus until urate crystals have been recovered therefrom (Fig 66). Sometimes its identity should be certified by the murexide test or histological study.

Areas of erosion of articular bone in gout represent replacement of bone by urates. Osseous tophi are uncommon in articular phase 1 fairly common in phase 2 and more numerous and larger in phases 3 and 4. Areas of erosion (replacement of bone by nonurate debris) may occur in rheumatoid arthritis osteoarthritis or lupus pernio. Hence erosions are not pathogno-

nomic for gout but if large or numerous they are usually gouty.

Sooner or later urate depositions affect certain renal tissues and constitute microtophi in the kidneys. On the distal side of the renal pelvic membrane urates may precipitate especially in acid urine coalesce and form urogenital gravel or stones. Urate deposits may affect tendons but not muscular tissues *per se*.

Except for exceedingly rare endocardial urate deposits the only certain examples of visceral gout are the urate accumulations and degenerative and inflammatory lesions in the kidney.

About 10 to 20 per cent of gouty patients develop gouty nephritis or renal colic or both. Hence suspect gout in cases of acute or chronic arthritis with renal colic or nephritis. Ulcerating tophi may complicate late gout and lead to amputation of digits.

The following are regarded as complications of gout by some as coincidental by others: acute thrombophlebitis (in 3.5 per cent of cases), acute ocular inflammation, hypertension (in 30 to 48 per cent), apoplexy, coronary thrombosis or sclerosis.

**Additional Laboratory Data.** Erythrocyte sedimentation rates may be normal between attacks and in mild attacks but elevated sometimes markedly in severe acute attacks and in chronic gouty arthritis. Serum concentrations of total cholesterol and esters are usually normal. The excretion of 17 ketosteroids in the urine may be subnormal. The levels of 17-corticoste-

FIG 65 Two tophi on ear

FIG 64 Severe chronic gouty arthritis with ulcerating tophi

motoring (pedaling) and sports True traumatic arthritis begins immediately after trauma the reaction is proportionate to the severity of trauma is confined to the traumatized region and is not relieved by colchicine characteristics of gout (history hyperuricemia tophi) are absent In post traumatic gouty arthritis the reaction is often delayed some hours is disproportionately severe after trivial trauma often progresses to other joints and is relieved by colchicine other characteristics of gout may be discoverable

Gouty arthritis is often provoked by acute dietary excesses associated with birth days weddings Thanksgiving New Year's Day conventions vacations and lodge night Potent provocatives are hunting and fishing trips with their trauma and indiscretions around the camp fire (meats venison liquor) The hunter may return home with game gun and gout Episodic excesses of

food and alcohol do not cause the gout *per se* any more than sugar causes diabetes but they may provoke symptomless gout and cause acute gouty arthritis Some attacks seems to be provoked by foods such as asparagus which are not rich in purines but may contain allergens

Surgical procedures commonly provoke acute gouty arthritis within the first seven postoperative days "In a case of acute postoperative arthritis suspect gout"

**Accumulation of Urates** The following data refer mainly to untreated gout The upper limits of normal values for serum urate in males are about 6 or 6.5 mg for females 5 or 5.5 mg per 100 ml According to certain writers once arthritis occurs hyperuricemia is present and persistent unless uricosuric agents are used But some observers have found normal serum urate concentrations in 15 to 20 per cent of gouty patients at various stages

mia develop? Three possibilities have been considered

1 Diminished Destruction of Urate. Uricase has never been found in man but small amounts of urate are destroyed in the intestines by bacteria. There is no convincing evidence that gouty persons are even less able than normal subjects to destroy urate.

2 Deficient Excretion. It was formerly believed that urinary urate excretion was often subnormal in gouty patients especially before acute attacks. But some gouty patients during and between attacks excrete more urate than nongouty controls. There is still considerable divergence of opinion as to the precise role of the kidney in the causation of hyperuricemia.

3 Increased Production. Biosynthesis of Uric Acid. Uric acid in man is not solely derived from ingested purines or nucleoproteins but can be synthesized from simple carbon and nitrogen compounds present in carbohydrate, protein and fat. Feeding experiments with glycine (a precursor of uric acid) labeled with  $N^{15}$  or  $C^{14}$  have demonstrated overproduction of urate in some but not in all gouty subjects tested. The evidence indicates that this excessive biosynthesis of urate from glycine ordinarily occurs by way of shunt pathways not involving incorporation into nucleic acids. Thus while a metabolic abnormality leading to excessive biosynthesis of urate has been shown to occur in some patients with gout, it is not possible as yet to generalize as to the cause of hyperuricemia in this disorder, nor is it known what determines the localization and timing of the precipitation of urate in the tissues.

*Pathogenesis of Acute Gouty Arthritis.* It is often assumed that there is a direct connection between hyperuricemia, urate deposits and acute articular attacks. According to some writers an acute attack develops either when urate crystals are suddenly precipitated *de novo* (from supersaturated blood or extravascular fluid) into previously uncontaminated articular tissues or when urates already present in articular cartilage suddenly burst into the joint space. But acute gouty arthritis is not a disease of the joint space; it is an intense inflammation of various articular and periarthritic tissues. Actually it is not known when urates are deposited whether long before just before during or between attacks. Massive infiltration of articular tissues by urate can be long present and painless. Why would articular tissues remain long tolerant of their (sometimes ex-

tensive) urate infiltration and then suddenly react *acutely* either when some of this old urate is extruded into the joint space or when a new crop of crystals is precipitated in the articular tissues?

In considering what relationship (if any) exists between urates and acute gouty arthritis this summary should be noted.

1 In gout the evolution of hyperuricemia does not necessarily parallel that of acute gouty arthritis. 2 The pattern of acute gouty arthritis does not necessarily parallel that of subcutaneous or intra-articular urate deposition. Thus (a) one patient with a few attacks develops extensive tophaceous gout and chronic gouty arthritis whereas another with many attacks develops few tophi and no chronic arthritis. (b) joints never affected acutely or chronically have been found at necropsy to be "whitewashed" with urates; spinal joints do not escape urate deposition but acute gouty spondylitis almost never occurs; and (c) per contra certain joints repeatedly attacked acutely have shown no gross urate deposits. 3 Acute attacks are unrelated to any consistent change in the urate concentration of blood or urine; serum and urinary urate do not change in any characteristic way just before or during attacks. 4 The anti-inflammatory and uricosuric effects of drugs useful in gout can be dissociated. Thus (a) acute attacks are relieved by certain antiphlogistic agents (for example colchicine) which have no proved direct effect on urate metabolism or at least on urate excretion; (b) acute attacks are not relieved by large uricosuric doses of probenecid; and (c) pyrazinamide which markedly decreases urate excretion and increases serum urate does not provoke acute arthritis even in the gouty (Villa et al.) and (d) the comparative effectiveness of cortisone, corticotropin, phenylbutazone and salicylates on attacks is not based on their relative uricosuric activity. 5 The hyperuricemia of leukemia, polycythemia and so forth usually remains symptomless. 6 Urates *per se* are relatively innocuous. Thus (a) peripheral tophi are usually painless; (b) acute arthritis is not provoked when urates are injected intravenously into nongouty persons or into gouty patients during or between attacks; and (c) urates injected subcutaneously are painless (Brown 1938) or are no more painful in the gouty than the nongouty (von Muller 1927). 7 Certain provocatives of acute gouty arthritis (such as purine-free liver extracts, Salyrgan, Gynergen, surgical operations) have little or no obvious connection

roids in the blood and urine are not far from normal (Villa *et al* 1958)

**Cause of Death.** Patients with mild gout and those responsive to prolonged therapy commonly live their full span of years and die from something coincidental to their gout. But there are many exceptions. Common causes of death are uremia from gouty nephritis; myocardial infarction and apoplexy.

**Roentgenographic Appearance.** The development of radiologically visible osseous tophi appears to be governed more by the gradient of articular vulnerability than by the general intensity of urate accumulation or the number and severity of attacks in any given joint. Even in severe gout when many proximal or less distal joints are extensively affected by urates (as shown later by necropsy) areas of erosion rarely become apparent roentgenographically except in the feet and hands. Such erosions appear occasionally in phase 1 (Fig 62) but commonly in phase 2 and thereafter. Because the appearance of erosions is often delayed roentgenograms of joints are of limited diagnostic usefulness. Periarticular thickening and nonspecific hypertrophic and destructive changes may involve joints sometimes in phase 1 but generally not until phase 2 and thereafter.

Roentgenograms of the kidneys are also of limited value—urate stones cast no shadow.

**Etiology and Pathogenesis.** *Dissociation of Clinical Features.* It is impossible to regard a single factor either an hereditary abnormality such as a gouty gene or one chemical substance such as urate as the prime cause of all features of gout. The dominant clinical features are (1) the acute articular attacks and (2) the accumulation of urate (with the renal and chronic articular consequences thereof). But temporal relationships between the two are far from close and their pathogenetic relationships are quite uncertain. Thus although the patterns of acute gouty arthritis and of urate accumulation often or commonly develop together at what might be called the same general rate, the evolution of the one does not necessarily parallel that of the other or depend on it. The two patterns are often dissociated. If so, the proximate causes of the two main features of gout may be quite separate and one is obliged to study separately the pathogenesis of each feature of the disease.

**Urate Accumulation.** *Etiology and Pathogenesis.* Nature and Extent. Isotopic techniques now permit more accurate measure-

ment of urate accumulations by estimation of the "miscible pool" of urate (Stetten). When a small measured amount of isotopically labelled uric acid of known concentration or isotopic abundance is injected intravenously into man it mixes freely with the body's natural urates, the degree of dilution depending chiefly on the total amount of urates momentarily present in the body. Calculation of this dilution measures the miscible pool, which is that quantity of urates in the body capable of mixing promptly with the injected urates and consequently of diluting the isotope. Among normals the miscible pool varies between 700 and 1400 mg (average about 1 gm) and about 500 to 850 mg of old uric acid is replaced daily by newly formed (unlabelled) urate. The turnover rate of 50 to 75 per cent. Among the few gouty patients studied to date the pool has always been increased, ranging between 1900 and 3400 mg in mild or moderate gout to over 30 000 mg in old severe untreated tophaceous gout. In a patient with severe tophaceous gout the miscible urate pool after irregular treatment was 18 450 mg (15 times normal) rose after 4.5 months without treatment to 31 000 mg, then fell to 2100 mg after the use of aspirin (2 to 4 gm daily) for three or four months (Benedict and co-workers). ACTH, cortisone or probenecid given for short periods reduced pools about 30 to 50 per cent and doubled the turnover rates by increasing renal clearance of urates and mobilizing the solid phase of miscible urates (Stetten).

**Hereditary Factor in Hyperuricemia.** Of 449 members of 87 gouty families, 21 per cent had clinical gout (arthritis and hyperuricemia or tophi), 15 per cent had symptomless hyperuricemia with no (other) signs of gout, and 64 per cent had neither hyperuricemia nor active gout. The conclusion is that inherent susceptibility to gout is transmitted by a single autosomal (that is not sex-linked) dominant (gouty or hyperuricemic) gene with a low penetrance in both sexes (Talbot 1940, Smyth and co-workers 1948, Stecher and co-workers 1949, 1957). Most nonhyperuricemic relatives do not develop hyperuricemia in later life.

Hyperuricemia usually does not appear until after puberty in males or near the menopause in females. Nonhereditary factors related to sex, renal function and normal androgenic activity are considered responsible for this change.

Regardless of its ultimate cause, by what mechanism does symptomless hyperuricemia

pletely Proper management and use of the drugs now available will retard or even reverse the process of urate accumulation prevent or heal the consequences thereof and also prevent or reduce the frequency and severity of acute attacks

**Prophylaxis and Treatment** Each phase and feature of gout requires its own treatment Measures for acute gouty arthritis are chiefly anti-inflammatory those for intertial gout (symptomless hyperuricemia and uratoses) are prophylactic and uricosuric those for chronic gouty arthritis are uricosuric and anti-inflammatory those for gouty nephritis renal colic or tophaceous ulcers are of a special nature

**Genetic Hyperuricemia of Gout** Should every case of idiopathic hyperuricemia (not due to renal insufficiency blood dyscrasias and the like) be diagnosed and if so treated as prearthritic gout? A presumptive diagnosis of pretophaceous prearticular gout is justified especially if the subject's family is gouty

How soon is prophylactic therapy indicated? It is postponed by some until the diagnosis is strengthened by the appearance of the first acute attack by others "until deposits of urates begin to declare themselves" "We would be doing the patient a disservice by starting him off on a lifetime of medication (Mason 1956)" However it may be presumed that the deposition of urate in the tissues usually begins before the first attack of acute gouty arthritis perhaps years before and before tophi (subcutaneous osseous renal) are discernible Since the total morbidity in a given case of gout can be great and the mortality from fatal gouty nephritis is impressive prophylaxis should be instituted in the writer's opinion as soon as a diagnosis of gouty hyperuricemia (pretophaceous prearticular) is made certainly for a male member of a gouty family and for anyone with tophi and renal (uratic) colic The prophylactic regimen is fairly simple relatively inexpensive and safe

**Acute Gouty Arthritis** Most important for the treatment of acute gouty arthritis is its recognition few conditions respond more promptly to appropriate measures

For suspected attacks Patients who recognize some characteristic nonarticular prodrome or wonder whether mild articular twinges represent an impending attack may abort it by taking orally a few doses of colchicine (0.65 mg every one to two hours) It is wiser to do this for a possible false alarm than to let an attack become established

For recognized attacks Affected parts should be protected by rest preferably in bed sometimes in a light splint or by a light wooden or metal cradle Activity or weight bearing should be curtailed until pain and tenderness are gone otherwise an exacerbation may result Hot water or ice-cold compresses (every two to three hours) are often preferable to dry heat compresses of magnesium sulfate or lead lotion are sometimes prescribed

**Colchicine** given orally is generally the treatment of choice But it is commonly misapplied Necessary for success are (1) prompt administration (2) proper total dosage and (3) proper rate of dosage so as to provide a maximal antiarthritic effect with minimal gastrointestinal irritation If individual doses are too large or too closely spaced gastrointestinal irritation may develop before articular relief is obtained If doses are too small or too widely spaced effective blood concentrations are not obtained The sooner colchicine is given the smaller is the total dose required and the better the chance for relief without significant gastrointestinal irritation

Colchicine tablets each containing 0.5 or 0.65 mg are prescribed thus two tablets initially and one tablet usually every two (waking) hours sometimes every hour or every three hours depending on individual responsiveness severity of attacks and probable "nearness" to toxicity Colchicine is given until gastrointestinal symptoms (diarrhea sometimes nausea or vomiting) appear If a second course is required two or three days should intervene between courses or until diarrhea subsides Some patients having learned their toxic or "diarrheal dose" (usually about six to four teen tablets) may be able in subsequent attacks to obtain a therapeutic without a toxic effect by taking one or two less tablets to a course If not and if trouble some diarrhea impends or develops codeine or paregoric may prevent or control it Patients should always keep colchicine tablets handy at home at the place of business and especially in the suitcase for travel emergencies If attacks are treated promptly relief may begin within a few (twelve to twenty four hours) and be more or less complete within about twenty four to seventy two hours But in severe attacks or in patients not responsive to colchicine symptoms may persist for days or even weeks

Colchicine given intravenously usually produces quicker results often without toxicity This is indicated (1) whenever rapid

with urates or with marked changes in urate metabolism

All these data suggest strongly that acute gouty arthritis bears little or no (direct) relationship to urates. But some precursor of urate might be responsible (Gutman).

**Pathogenesis of Chronic Gouty Arthritis** Tissue reactions to foreign matter (tophaceous deposits) in and around joints are considered responsible for the slow development of chronic gouty arthritis.

From the foregoing it would appear that urates may have little or nothing to do with acute gouty arthritis but everything (more or less) to do with chronic gouty arthritis and that chronic gouty arthritis is not the end result of acute gouty arthritis or the sum total of acute attacks but that acute and chronic gouty arthritis may be quite unrelated to each other each having a different immediate cause and an independent (though sometimes parallel) evolution. The same can be said for the relationship between acute gouty bursitis (for example olecranon) and chronic tophaceous bursal thickenings painless or painful.

**Pathogenesis of Gouty Nephritis** Renal dysfunction is considered the cause of gout by some the result of gout by others. Whether or not the undefined "primary renal dysfunction" in the minds of the former is purely hypothetical or will some day be demonstrated it is not to be confused with the secondary renal dysfunction of gouty nephritis—a late characteristic of gout. Intrarenal urate deposits presumably elicit a foreign body tissue reaction. Varying degrees of dysfunction and destruction of renal units result superimposed thereon may be secondary infection. Changes in the renal vasculature due to hypertension or to aging also play an important role.

**Pathogenesis of Vascular Complications** The vascular lesions which may complicate severe or late gout bear no direct or obvious histopathological relationship to urate at least urate is practically never found therein. The mechanism of their production is unknown.

**Adrenocortical Anterior Pituitary or Hypothalamic Dysfunction** The hypothesis has been advanced that gout is an endocrine disease characterized by deficiency of 11 oxysteroids that is chronic relative lack of 11 oxysteroids is characteristic of symptomless interval gout and that an even greater acute deficiency is related to acute attacks. Since the adrenal cortices appear to be normally responsive in gout

at least to exogenous ACTH the hypothetical dysfunction is said to involve either the anterior pituitary or more likely the hypothalamus with sluggishness in providing enough endogenous ACTH to satisfy the 11 oxysteroid requirements put upon the gouty patients by various stresses.

No adrenocortical dysfunction during or between attacks has been found by other workers. Colchicine does not increase adrenocortical activity. Clinically recognized disorders of the anterior pituitary or adrenals either with hypofunction or hyperfunction are not associated with gout. The urinary excretion of 17 ketosteroids is subnormal in most but not all cases of gout if this results from some adrenocortical or gonadal abnormality the nature and role of this abnormality are unknown. There is as yet no indisputable evidence that pituitary or adrenocortical dysfunction plays a primary role in the pathogenesis of gout.

**Diagnosis** The presence of any characteristic feature (podagra, hyperuricemia, peripheral tophi, erosions) is of great diagnostic significance but the appearance of any one is often delayed until rather late in the disease. The metatarsophalangeal joint of a great toe is affected early or repeatedly in some cases rarely or never in others. Also hyperuricemia is usually present but one must not insist on its presence or that of podagra before diagnosing gout. Usually a long rather than a short time elapses between "toe and tophus". The pattern of recurrent arthritis with complete remissions is of itself so distinctive as to be almost pathognomonic although episodic rheumatoid arthritis and palindromic rheumatism must be excluded. If diagnosis of any single attack is not helped by the history of previous attacks or if the initial attack is under consideration diagnosis is based on the characteristics of an attack as described including predisposing and provocative factors. If an attack promptly responds to treatment (especially to colchicine specific for gout) the diagnosis of gout is justified even before the development of tophi.

**Prognosis** Prognosis is best when gout is first manifest late in life poorest when symptoms begin before the age of twenty or twenty five years. But estimation of prognosis is difficult. In the untreated disease the frequency of attacks and the rate of urate accumulation may change capriciously. The disease sticks to him till death wrote Aretaeus about 1600 years ago. This is still true but now one can do much to control gout largely if not com-

hours Treatment is seldom required after the fourth day (Freyberg and Smyth 1958) Large doses also have a moderate uricosuric effect (Gutman and Yu Kidd and co workers Kuzell and co workers)

Chief limitations are the toxic reactions which increase with length of treatment Toxic reactions affected 13 per cent of patients treated briefly for acute gouty arthritis and 32 per cent of those treated longer for chronic gouty arthritis reactions necessitated cessation of treatment in 4 and 8 per cent respectively Reactions include edema nausea epigastric pain morbilliform rash granulocytopenia and activation of peptic ulcer The drug is contraindicated whenever edema from cardiac renal or hepatic disease might develop

The old concept that attacks are related to urate retention and precipitation led to the use of uricosuric agents in acute gouty arthritis the rationale of which is by no means established Except for cortisone and ACTH (which appear to control attacks by anti-inflammatory rather than by uricosuric action) uricosuric agents do not certainly prevent or control acute gouty arthritis Indeed acute attacks are sometimes precipitated by diuretic or uricosuric agents (salicylates cinchophen mersalyl [Saltyrgan] probenecid) Despite its uricosuric effect probenecid (Benemid) is of no value for acute attacks indeed their incidence may increase during the early weeks of such therapy

There are no clear indications for a special diet during the attack of acute gouty arthritis A low purine diet a large intake of fluid and avoidance of alcohol are usually prescribed

*Interval Treatment of Symptomless Gout* Interval treatment aims to reduce the number and severity of attacks to retard or even reverse the process of urate accumulation and to prevent or postpone the late sometimes critical renal complications These intentions require the use not of a single remedy but of several measures combined

Preventive measures include the use of colchicine and the avoidance reduction or control of the psychic medicinal alcoholic dietary traumatic and surgical provocatives of acute gouty arthritis The more or less continuous use of colchicine in nonirritating doses is of prophylactic value (Cohen 1936 Gutman and Yu 1952) For mild cases (less than one attack yearly) one tablet (0.5 mg) is given once daily for three or more days a week for moderate cases (more than one attack yearly) 0.5

mg once daily throughout the week for severe cases two or three tablets are given daily more or less continuously (Talbot 1958) Sometimes this made the difference between virtual incapacitation and relatively normal activity Patients have taken colchicine daily for 5 to 10 years without discomfort or drug tolerance (Kersley and co workers 1950 Talbot 1942 1957) Most patients continue to tolerate about 1.3 to 2.6 mg colchicine daily occasionally less

Postoperative gouty attacks can generally be prevented by use of either a high carbohydrate purine free diet and salicylates for five days before and five days after operation (Hench) or colchicine (0.5 mg three times a day if given orally or 1.5 mg once a day if given intravenously) for at least three days before and after operation (Kersley and co workers 1950 Talbot) or ACTH (with or without colchicine orally) for two to three days before and after operation (Coste and co workers)

*Diet* Opinion on the rationale of diets in gout is undergoing revision The chief aim of dietary management in recent years usually has been not so much to relieve or to prevent acute attacks as to assist in counteracting hyperuricemia and the deposition of urate in the tissues Ingested purines are a rich source of urate ingested protein contributes significantly to urate production a diet high in fat decreases renal excretion of urate carbohydrates foster urate excretion but excesses produce obesity to be avoided Taking these considerations into account the diet commonly recommended for interval gout is low in purines and fats adequate in proteins (50 to 75 gm daily) especially in purine free proteins and generous but not excessive in carbohydrates In such a diet would be cereals grain products eggs cheese milk fruits and nonleguminous vegetables to which could be added one serving of meat fish or fowl five days a week (Gutman and Yu Hench) Patients with a life time disease would hardly accept a more restrictive diet moreover since man can synthesize urate not only from purines but also from purine free proteins (as the labeled glycine experiments demonstrate) carbohydrates and fats there are definite limits to the effectiveness of any diet however restrictive in reducing urate biosynthesis

Deficiencies in protein iron and vitamin B must be avoided generally gout diets should be reinforced with an approved vitamin preparation for example one hexa

relief is particularly desirable (2) when good results from colchicine given orally are complicated by marked gastrointestinal irritation (3) for acute postoperative attacks (4) for attacks unresponsive to colchicine given orally perhaps belatedly. Individual doses have varied from 0.65 mg once to three times daily to 3 mg once daily the latter is the most effective (Graham and Roberts Ward). Patients often require only one or two injections occasionally more. Relief may begin within an hour or two of the first injection is often notable within six to twelve hours and is more or less complete within eighteen to thirty six hours (Ward). Gastrointestinal irritation rarely develops from one or two injections (1.5 to 3 mg each eight to twenty four hours apart) but may be mild or moderate if several injections are required. Colchicine is very irritating if injected outside the vein.

Corticotropin (ACTH) (aqueous) in sufficient doses rapidly controls most acute attacks even those unresponsive to colchicine. If enough ACTH or cortisone is given long enough attacks are usually controlled without relapses. Misnamed withdrawal flares are simply relapses of attacks caused by premature discontinuance of temporarily adequate treatment or discontinuance of doses which were never adequate and are not due to ACTH induced pituitary adrenal insufficiency as has been stated.

If aqueous ACTH is used alone (that is without colchicine) recommended doses are for the first day 100 to 200 mg (in divided doses) depending on the attacks severity for the next three days or so 80 to 120 mg daily. Thereafter even though symptoms are more or less completely controlled use of ACTH should be continued though in progressively smaller daily doses for four to eight more days total treatment lasting about a week or two. Colchicine resistant attacks or attacks which develop despite prophylactic use of colchicine between attacks often require larger doses of ACTH than otherwise. From adequate doses relief begins often within four hours of the first dose may be marked (75 to 90 per cent relief) within twenty four hours and complete within twenty four to seventy two hours. Even so the attack though symptomatically suppressed has generally not run its full course until a week or two have passed. It is advantageous to give colchicine in doses of 1 mg daily by mouth as the dose of ACTH is lowered and to continue this after administration

of ACTH is terminated in order to prevent exacerbations of acute gouty symptoms.

Attacks are controlled with long acting ACTH gels given intramuscularly once daily (total doses comparable to those of aqueous ACTH) or with ACTH given by intravenous infusion (20 to 30 USP units in 500 ml of fluid over a period of six to eight hours).

According to some writers cortisone is inferior to ACTH—indeed relatively use less. Consequently relatively few patients have been treated with cortisone given intramuscularly and even fewer with cortisone hydrocortisone or prednisone tablets given orally despite great practical advantages. Unsatisfactory results have been largely from underdosage or premature discontinuance. If enough cortisone is given long enough most attacks are controlled promptly. Rapid relief without relapses has resulted from cortisone given occasionally for only three to four days but generally for one to three weeks. Successful doses have been either 200 to 300 mg daily for the first three to four days then progressively smaller doses for one to two weeks more or 100 mg daily for about two to three weeks.

The combined use of cortisone and colchicine has been effective. 100 mg of cortisone in divided doses and 2 mg of colchicine (0.65 mg three times daily) for a week or more. Relapses due to premature discontinuance of cortisone (used alone) have been controlled either by giving cortisone a few more days or by giving cortisone plus colchicine.

Prednisone has given very satisfactory results in daily doses of 25 mg or more. Less satisfactory results were obtained with smaller doses.

Attacks have been controlled promptly by injections (often one only) of 25 to 50 mg of hydrocortisone acetate into gouty joints or bursae (Hollander).

Phenylbutazone (Butazolidin) is also effective when given intramuscularly 0.6 to 1.0 gm (generally the latter) once daily or orally 100 to 800 (generally 400 to 600) mg daily in four divided doses. The oral preparation is convenient and effective particularly when given in a schedule which provides 600 mg as a first (priming) dose and 200 mg at two- to four hour intervals thereafter until a response is obtained. Inflammation usually lessens within a few hours after the first dose. Pain is controlled generally within twenty four hours. The attack may disappear within seventy two

hours Treatment is seldom required after the fourth day (Freyberg and Smyth 1958) Large doses also have a moderate uricosuric effect (Gutman and Yu Kidd and co-workers Kuzell and co-workers)

Chief limitations are the toxic reactions which increase with length of treatment Toxic reactions affected 13 per cent of patients treated briefly for acute gouty arthritis and 32 per cent of those treated longer for chronic gouty arthritis reactions necessitated cessation of treatment in 4 and 8 per cent respectively Reactions include edema nausea epigastric pain morbilliform rash granulocytopenia and activation of peptic ulcer The drug is contraindicated whenever edema from cardiac renal or hepatic disease might develop

The old concept that attacks are related to urate retention and precipitation led to the use of uricosuric agents in acute gouty arthritis the rationale of which is by no means established Except for cortisone and ACTH (which appear to control attacks by anti-inflammatory rather than by uricosuric action) uricosuric agents do not certainly prevent or control acute gouty arthritis Indeed acute attacks are sometimes precipitated by diuretic or uricosuric agents (salicylates cinchophen mersalyl [Salyrgan] probenecid) Despite its uricosuric effect probenecid (Benemid) is of no value for acute attacks indeed their incidence may increase during the early weeks of such therapy

There are no clear indications for a special diet during the attack of acute gouty arthritis A low purine diet a large intake of fluid and avoidance of alcohol are usually prescribed

*Interval Treatment of Symptomless Gout* Interval treatment aims to reduce the number and severity of attacks to retard or even reverse the process of urate accumulation and to prevent or postpone the late sometimes critical renal "complications" These intentions require the use not of a single remedy but of several measures combined

Preventive measures include the use of colchicine and the avoidance reduction or control of the psychic medicinal alcoholic dietary traumatic and surgical provocatives of acute gouty arthritis The more or less continuous use of colchicine in nonirritating doses is of prophylactic value (Cohen 1936 Gutman and Yu 1952) For mild cases (less than one attack yearly) one tablet (0.5 mg) is given once daily for three or more days a week for moderate cases (more than one attack yearly) 0.5

mg once daily throughout the week for severe cases two or three tablets are given daily more or less continuously (Talbot 1958) Sometimes this made the difference between virtual incapacitation and relatively normal activity Patients have taken colchicine daily for 5 to 10 years without discomfort or drug tolerance (Kersley and co-workers 1950 Talbot 1942 1957) Most patients continue to tolerate about 1.3 to 2.6 mg colchicine daily occasionally less

Postoperative gouty attacks can generally be prevented by use of either a high-carbohydrate purine free diet and salicylates for five days before and five days after operation (Hench) or colchicine (0.5 mg three times a day if given orally or 1.5 mg once a day if given intravenously) for at least three days before and after operation (Kersley and co-workers 1950 Talbot) or ACTH (with or without colchicine orally) for two to three days before and after operation (Coste and co-workers)

*Diet* Opinion on the rationale of diets in gout is undergoing revision The chief aim of dietary management in recent years usually has been not so much to relieve or to prevent acute attacks as to assist in counteracting hyperuricemia and the deposition of urate in the tissues Ingested purines are a rich source of urate ingested protein contributes significantly to urate production a diet high in fat decreases renal excretion of urate carbohydrates foster urate excretion but excesses produce obesity to be avoided Taking these considerations into account the diet commonly recommended for interval gout is low in purines and fats adequate in proteins (50 to 75 gm daily) especially in purine free proteins and generous but not excessive in carbohydrates In such a diet would be cereals grain products eggs cheese milk fruits and nonleguminous vegetables to which could be added one serving of meat fish or fowl five days a week (Gutman and Yu Hench) Patients with a life time disease would hardly accept a more restrictive diet moreover since man can synthesize urate not only from purines but also from purine free proteins (as the labeled glycine experiments demonstrate) carbohydrates and fats there are definite limits to the effectiveness of any diet however restrictive in reducing urate biosynthesis

Deficiencies in protein iron and vitamin B must be avoided generally gout diets should be reinforced with an approved vitamin preparation for example one hexa

vitamin capsule USP every one or two days Normal weight should be maintained and obesity avoided or corrected Coffee and tea are permissible

Fortunately control or reversal of uricosis can now be accomplished more effectively by uricosuric agents than by diets Hence there is a growing leniency with respect to the eating habits of gouty persons Nevertheless it is still logical to decrease the purine load on the kidneys and other tissues by avoidance of purine rich foods and excesses of proteins and fats Of course any food or alcoholic drink which (regardless of purine content) seems repeatedly to provoke attacks should be avoided Temperance rather than abstinence from alcohol is commonly recommended

For prolonged uricosuria *probenecid* a benzoic acid derivative currently is considered the best agent (Gutman and Yu Talbott) Serum urate is decreased and excretion of urinary urate is notably increased by suppression of tubular resorption For uricosuria *probenecid* (Benemid) (2 gm daily) is much more effective than *neocinchophen* (3 gm daily) or *aspirin* in small doses (2 to 3 gm daily) and more effective than *aspirin* 5 gm daily but less effective than *aspirin* or *sodium salicylate* plus *sodium bicarbonate* 5 gm of each daily

Doses of *probenecid* are 0.5 to 2 gm or more daily Most toxic reactions are minor they include nausea anorexia constipation and rash Allergic reactions sometimes develop One severe reaction (headache muscular aching pruritus dyspnea nausea vomiting chill fever) developed after ten days of therapy (2.0 gm daily) and recurred later after a single test dose of 0.125 gm (Kloemphen and Montgomery 1952) Larger doses (2.0 gm daily) are rarely needed unless renal insufficiency or extensive tophaceous deposits are present Patients should receive also a liberal fluid intake and *sodium bicarbonate* (about 2 to 5 gm daily) to prevent renal gravel *Probenecid* and *salicylates* should not be given concurrently each counteracts the uricosuric effect of the other (Gutman and Yu 1951 Pascale and co-workers) ACTH does not interfere with *probenecid*

*Probenecid* tends to provoke gouty arthritis during the first weeks of treatment (in 18 per cent of cases) thereafter attacks may become fewer than before treatment Vigorous uricosuria from overzealous dosage together with insufficient fluids and alkalis may produce a momentary "flash

colic" a true renal colic or urate crystal luria and hematuria

Marked uricosuria is produced by *aspirin* or *sodium salicylate* in daily (divided) doses of 4 to 6 gm or more but not by daily doses of less than 3 or 4 gm (Hanzlik 1927 Graham 1920 1933) *Salicylates* inhibit tubular resorption of urate The uricosuric effect of *salicylates* may be enhanced by the concurrent use of *sodium bicarbonate* (Gutman 1950) Prolonged use of *aspirin* or *sodium salicylate* (about 15 gm four times a day) and *sodium bicarbonate* (13 gm four times a day) may be recommended for those few who tolerate such amounts without *salicylism* *Sodium bicarbonate* is given (1) to increase the solubility of urinary urates so as to prevent the spontaneous or therapeutically induced formation of uratic calculi or (2) to enhance *salicylate* uricosuria *Sodium bicarbonate* occasionally produces gastrointestinal symptoms erroneously ascribed to the uricosuric agent Then an alternate method of urinary alkalization is necessary

The prolonged use of the cortisones corticotropins *cinchophen* and *phenylbutazone* as uricosuric agents is not recommended

*Chronic Gouty Arthritis* Joints "washed with urates can be symptomless Where and whether chronic inflammation appears depends on at least two factors tissue receptivity to urate deposition and tissue vascularity Urate deposits are not found in tissues of the central nervous system or in muscle tissue *per se* (except at tendinous attachments) *Chronic granulomatous inflammation* develops around urate deposits in vascularized tissues (synovial bone marrow) but not in avascular tissues (hyaline and fibrous cartilage) (Collins 1951) But in articular cartilage degeneration may develop *Per contra* the characteristic pathology of acute gouty arthritis is an acute cellular inflammation with or without urate crystals or any chronic foreign body cell reaction

For the prevention and treatment of chronic uratic gouty arthritis measures must be directed against two known factors the uricosis and the resulting chronic inflammation present or impending The prevention of future urate deposits and the slow (partial) mobilization and excretion of some of those already present are accomplished to some degree at least by avoidance of foods rich in purine and continual administration of *probenecid* or other uricosuric agent Prolonged use of a uri

cosuric agent has reduced the size of subcutaneous tophi healed tophaceous ulcers and fostered the sclerotic repair of osseous tophi (Gutman and Yu 1952). To the extent that uricosuric agents can reduce the articular uratoses which may provoke chronic inflammation and degeneration they can relieve chronic uratic arthritis slowly and indirectly. But the supplementary use of anti-inflammatory agents is usually or often indicated.

After symptomatic chronic gouty arthritis has developed the patient is still subject to recurring attacks of acute gouty arthritis. The nature and proper treatment of the latter are usually recognized when an attack suddenly involves joints unaffected by chronic gouty arthritis. But when upon the latter is superimposed a sudden acute attack which is mistaken for an exacerbation of the chronic uratic arthritis anti-inflammatory measures may be neglected in favor of rest, physical therapy, probenecid and so forth. It is important therefore to distinguish between chronic (uratic) gouty arthritis (type of inflammation and symptoms) and exacerbations thereof and a case of chronic uratic arthritis complicated temporarily by a superimposed acute gouty (nonuratic) arthritis.

Chronic (uratic) gouty arthritis (including true exacerbations thereof) appears not to be relieved by colchicine. But it may be amenable to the prolonged use of phenylbutazone, daily maintenance doses of 100 to 200 mg (de Seze et al 1958). Intra-articular injections of phenylbutazone 400 mg gave "striking results" when an acute inflammatory episode supervened in chronic gouty arthritis of the knees. What ever part of a supposed "flare" of chronic uratic arthritis is rather promptly relieved by the usual anti-inflammatory measures (colchicine intravenously or orally, ACTH, cortisone or prednisone, hydrocortisone intra-articularly, phenylbutazone orally, intramuscularly or intra-articularly) is that part representing an inflammatory reaction to the nonuratic noncrystalline (rather than to the uratic) irritant of articular gout. It is not unreasonable to suppose that in severe cases the two types of inflammation combine to produce a chronically painful joint. Except for colchicine (useful only against acute nonuratic inflammation) and probenecid (useful only against uratoses) the antigout (anti-inflammatory) medications appear to be nonspecific.

**Gouty Nephritis: Prevention and Treatment.** Prolonged administration of a uricosuric agent is useful for the prevention

and treatment of uratic renal lesions as are also abundant intake of fluids especially water and constant alkalinization of the urine. Special measures are required for pyelonephritis, renal insufficiency or uremia.

**Vascular Accidents: Prevention and Treatment.** One can only speculate on the mechanism or agent responsible for vascular complications. For their prevention the physician must rely on the general regimen already outlined.

**Treatment of Gross or Ulcerating Tophi.** Special treatment is required for some tophi such as painful ones on weight-bearing surfaces, large ones which prevent use of regular shoes or gloves or some in which fistulous ulcers are present or impending. Prolonged therapeutic uricosuria may heal draining sinuses. If tophi remain troublesome they should be excised. The removal of a small tophus under local anesthesia can be done usually without a postoperative flare. But when one or more large tophi are to be excised and if general anesthesia is used one should institute prior to tophectomy a regimen to prevent acute postoperative (that is post-tophectomy) gouty arthritis.

**Results of Therapy.** Although gout is not yet curable its important manifestations are now largely controllable if treatment is planned carefully, applied early and with appropriate modifications continued resolutely. Available is impressive clinical and photographic evidence that the progress of hyperuricemia and uratoses can be not only retarded but kept "in reverse" with normalization of uricemia, prevention of new and reduction in the size of old subcutaneous tophi, nonsurgical healing of tophaceous ulcers and the prevention or lessening of symptom-producing chronic arthritis.

## Diabetes Insipidus

**Definition** Diabetes insipidus is the clinical state resulting from a deficiency of antidiuretic hormone (vasopressin). Its principal features are the persistent excretion of large volumes of a dilute but otherwise normal urine, unrelenting thirst and compensatory polydipsia. There is no intrinsic renal disease and replacement therapy usually relieves the symptoms promptly.

**Incidence and Etiology** This relatively rare condition can be inherited or acquired. The hereditary type, which accounts for about 2 per cent of all cases, is transmitted as a dominant character with poor penetrance in the female, that is more commonly in males and with skipped generations. Acquired diabetes insipidus may result from any lesion which damages or destroys any of the essential structures of the hypothalamo-neurohypophyseal system. Approximately one third of the cases are attributable to primary or metastatic intracranial neoplasms and one third to a wide variety of lesions (traumatic post-operative infectious vascular granulomatous etc.); one third are without apparent cause or demonstrable pathological findings.

**Physiology** Increasing evidence supports the view that both the elaboration and release of antidiuretic hormone are effected by neurons of the supraoptic and paraventricular nuclei of the hypothalamus. Scharrer and his colleagues maintain that the hormone originates in the hypothalamic nuclei as neurosecretory material which migrates along the axons to be stored in their terminations in the neurohypophysis.

The rate of release of antidiuretic hormone is modified by many influences such as (1) remote activities in the central nervous system resulting from emotion, pain or exposure to cold; (2) the osmoreceptors described by Verney which are exquisitely sensitive to changes in the osmolarity of blood perfusing the internal carotid arteries; (3) a variety of chemical agents which suppress (alcohol) or promote the release of hormone (nicotine morphine phenobarbital ferritin BAL etc.).

Although the exact site and mode of action of vasopressin remain conjectural, it is generally accepted that the hormone

causes an increased reabsorption of water from tubular urine without altering either glomerular filtration or the excretion of electrolytes. There is no evidence that vasopressin influences the reabsorption of water in the proximal convoluted tubule. Recent studies on frog skin indicate that the hormone is capable of opening or widening "pores" in the membrane to facilitate the passive movement of water along osmotic gradients. A similar mechanism has been suggested by some investigators to account for its action in the renal tubule. According to this view, vasopressin is believed to increase the passive reabsorption of water which follows the active transport of electrolytes (cf. section on Renal Physiology and Tests of Renal Function).

The urine volume in diabetes insipidus is dependent in part on the quantity of solutes such as urea and electrolytes which must be excreted. Inability to elaborate a urine of more than very limited concentration necessitates an increasing excretion of water with an increasing solute load. Coincident destruction of the anterior lobe of the hypophysis lessens the severity of diabetes insipidus by decreasing the solute load presented to the tubules. This occurs as the result of both a reduction in glomerular filtration rate and a decreased dietary intake of protein and salts.

**Diagnosis** In general the diagnosis of true diabetes insipidus can be established with certainty only when the following criteria are fulfilled: (1) a history of persistent polydipsia and polyuria with daily urine volumes of 5 to 20 liters; (2) a consistently low urinary specific gravity which cannot be raised above 1.010 by the withholding of fluids; (3) a failure to evoke significant antidiuresis by stimuli such as hypertonic saline or nicotine which promote the release of hormone from a functional neurohypophyseal system; and (4) the administration of 0.1 unit of Pitressin causes antidiuresis and urine concentration. Water deprivation, which results in an increase in the serum sodium concentration, has been largely abandoned as a routine test procedure because of the intolerable thirst and occasionally dangerous dehydration which may result. In the test devised by Hickey and Hare, the intravenous infusion of hypertonic saline (0.25 ml of 5 per cent sodium chloride per kg of body weight per minute for 45 minutes) after the establishment of water diuresis induces antidiuresis in normal subjects but not in patients with diabetes insipidus. It is a valuable test when carefully performed.

but its use is contraindicated in patients with coexistent cardiovascular disease. The inhaling of 1 to 3 cigarettes and the subcutaneous injection of 1 to 3 mg of nicotine tartrate have also been employed as stimuli to provoke antidiuresis in the hydrated subject. In interpreting the results of this test account should be taken of the patient's smoking habits and it should be appreciated that transitory antidiuresis may occur even in diabetes insipidus if nicotine produces an abrupt drop in blood pressure and glomerular filtration rate. Parenteral nicotine should not be administered to patients with coronary insufficiency. It is important to recognize that a relatively mild diabetes insipidus occurs occasionally from a partial deficiency of antidiuretic hormone. In such instances both the hypertonic saline and nicotine tests may cause antidiuresis and elevation of the urine specific gravity but not to the degree observed in normal subjects.

Patients with primary psychogenic polydipsia present the commonest problem in differential diagnosis. Diabetes insipidus can usually be excluded by a history of gradually increasing polydipsia and polyuria often by the relief of symptoms with placebo preparations and by normal responses to the tests already discussed.

Roussak, Oleesky and others have described a diabetes insipidus-like syndrome occurring in the course of chronic renal disease and have designated this condition "water losing nephritis." Williams and Henry have introduced the term nephrogenic diabetes insipidus to indicate a familial probably sex-linked disorder occurring in males in which polydipsia and polyuria begin in infancy. In addition diabetes insipidus-like states have been observed in potassium deficiency and following excessive doses of desoxycorticosterone acetate or cortisone. In all of the foregoing syndromes the polyuria is largely unaffected by the administration of Pitressin and diagnosis should not be difficult if these possibilities are considered.

**Treatment.** Replacement therapy is available in three types of preparations: desiccated posterior pituitary powder, a soluble aqueous extract and Pitressin tannate in oil. The nasal insufflation of 10 to 50 mg of the powder several times each day usually provides effective control of the symptoms. This is a convenient and economical form of therapy but nasal irritation frequently prevents its continued use. The aqueous extract is commonly employed in diagnostic procedures but in replacement

therapy it must be injected subcutaneously at intervals of four to twelve hours and its rapid absorption from the injection site may produce unpleasant musculotropic effects on the gastrointestinal tract. The sparingly soluble Pitressin tannate suspended in vegetable oil provides effective therapy when injected subcutaneously in doses of 0.2 to 0.4 ml every two to three days. This is currently the regimen most widely employed. Occasional individuals exhibit allergic reactions to the posterior pituitary preparations. It should be emphasized that water intoxication is a potential complication of parenteral administration whether diagnostic or therapeutic. Although the patient with diabetes insipidus usually decreases his fluid intake as polyuria is controlled the psychogenic water drinker may not.

## Diabetes Mellitus

**Definition.** The disease known as diabetes mellitus is a disorder of carbohydrate metabolism characterized by hyperglycemia and glycosuria. This disorder is associated with a disturbance of the normal insulin mechanism. When carbohydrate metabolism becomes seriously deranged there are readily demonstrable abnormalities of protein and fat metabolism. The latter may give rise to ketosis, acidosis, coma and death. The disturbance in the insulin mechanism is believed to be due in some cases to a decrease in the elaboration of insulin by the pancreas and in others it probably results from an increase in insulin requirement by the tissue cells to maintain normal carbohydrate metabolism.

**History.** The growth of our knowledge of diabetes mellitus demonstrates admirably a pattern of science

tific development which has led repeatedly to significant medical progress. Clinical description of the disease came first Aretaeus appropriately described a melting down of the flesh and limbs to urine. The first and crude demonstration of the chemical nature of the disorder is ascribed to Susruta who in the fifth century described honey urine as confirmed by Thomas Willis 1200 years later and to Dobson who in the eighteenth century demonstrated the presence of sugar in the urine. The third significant step was the physiological demonstration by von Mering and Minkowski in 1889 that extirpation of the dog's pancreas was followed by the development of a condition strikingly similar to diabetes in man. Hyperglycemia glycosuria and ketonuria appeared and when glucose was fed it was excreted quantitatively in the urine. After this histopathological studies in man by Opie in 1900 showed some degree of correlation between degeneration of islet tissue in the pancreas and the presence of diabetes. This was supported by the experiments of Ssobolew who in 1902 demonstrated that degeneration of the tryptic portion of the pancreas did not result in diabetes.

The final step which appeared to establish the proof that diabetes mellitus arises from intrinsic disease of the pancreas was accomplished by the classic studies of Banting a surgeon and Best then a medical student in 1921. They prepared an extract of the islet tissue of the pancreas when the tryptic portion had degenerated after ligation of the pancreatic ducts. This extract depressed the blood sugar of the diabetic dog as had extracts prepared by Zuelzer in 1907 and others at later dates from whole pancreatic tissue. These extracts were undetectable in terms of toxicity but preparations safe for clinical use were soon prepared by alcoholic extraction procedures developed by J. B. Collip a member of Banting's group. With the development of insulin which corrected the disturbances of carbohydrate metabolism in diabetic dogs and humans it was believed that all the riddles of diabetes mellitus had been solved.

Further study has shaken this confidence and suggests that diabetes mellitus may be more complex than it appeared to be immediately after the discovery of insulin and that intrinsic disease of the pancreas may not in most cases be the primary cause after all. These misgivings which arose on the basis of clinical observations in a variety of endocrine disorders received impressive support in the startling experiments of Houssay. This investigator in 1930 found that the severe diabetes resulting from pancreatectomy in the dog was greatly ameliorated if the pituitary gland was subsequently extirpated. Long and Lukens later demonstrated the same improvement when instead of the pituitary the adrenal glands were removed in pancreatectomized cats. It appeared therefore that the elaboration of insulin was essential for the control of hyperglycemia glycosuria and ketosis only when the adrenal or pituitary glands were present. More recently total pancreatectomy has been performed in man and it appears that whereas this procedure results in the development of diabetes the intensity of the process as judged by insulin requirements is considerably less than in patients with the spontaneously occurring disease in whom the pancreas at autopsy may show only minor change. Thus the simple hypothesis which appeared both satisfactory and adequate four decades ago yields to uncertainty and complexity and constitutes a challenge to future investigators.

**Incidence** Surveys of Wilkerson and others indicate a prevalence rate of diabetes

of between 14 and 17 per cent. Thus there are probably in excess of 2,000,000 overt cases in the United States. The potential reservoir of diabetes is considerably in excess of this since a number of studies show that many persons with borderline postprandial hyperglycemia in subsequent years develop the typical disease.

Since the advent of insulin the total mortality from diabetes is reported to have increased; the death rate in the period from 1935 to 1940 alone increased from 22.5 to 26.6 per 100,000. This can undoubtedly be ascribed in part to the general increase in life expectancy which increases the number of people who acquire diabetes in later life and also to the greater accuracy of the diagnosis of diabetes. In contrast to the reported increase in diabetic deaths in persons more than fifty years of age is the sharp decrease in the diabetic death rate in the earlier decades. This can be credited wholly to insulin therapy. Whereas patients formerly died at an early age they now live to become victims of the arteriosclerotic period of life.

**Age** Diabetes may develop at any age but the curve of incidence reaches its peak in the fifth and sixth decades. According to Joslin approximately 50 per cent of all diabetes occurs between the ages of forty and sixty years. Only 1 per cent occurs in the first decade and 3 per cent in the eighth.

**Sex** Between the ages of forty and seventy years diabetes is significantly more common in women than in men the ratio being approximately 3 to 2. In earlier life there appears to be a slight preponderance in males. It is possible that the high incidence in women more than forty is related to the high incidence of obesity in this group.

**Etiology** It must be emphasized at the outset that the etiology of diabetes mellitus is undetermined in the vast majority of patients. However it is apparent from experimental studies and clinical observation that a number of factors may disturb the normal insulin mechanism and thereby induce the hyperglycemia and glycosuria typical of diabetes. For this reason it might be more accurate to consider the etiology of diabetes.

The capacity to metabolize carbohydrate as well as other substances must be considered a fundamental process inherent in most if not all tissue cells. This property probably constitutes a heritage from our unicellular ancestors. What part primary disturbances of the intrinsic enzyme sys-

terms concerned with these oxidative processes may play in diabetes mellitus is still obscure. It is known however that certain endocrine glands through the elaboration of their respective hormones are able to influence profoundly the metabolism of various foodstuffs; therefore the relations of these glands to the origin of diabetes must be considered.

*The Pancreas* Insulin is elaborated by the beta cells of the islands of Langerhans in the pancreas. It is therefore to be expected that total pancreatectomy will terminate insulin production, thus giving rise to severe and rapidly fatal diabetes. This is true in the dog, but in other species the diabetes induced by pancreatectomy is much less intense.

Total pancreatectomy in man has been performed on a number of occasions. Diabetes appears promptly after this procedure, but in contrast to that in the dog is not of great severity. Patients may require 25 to 50 units of insulin daily with a liberal ingestion of carbohydrate. This dosage of insulin as already stated is considerably less than that required by many patients suffering from diabetes of spontaneous origin. Hence it is probable that factors other than a decrease in liberation of insulin from beta cells of the islets contribute to the severity of diabetes in many patients. For example, in certain cases primary abnormalities in the cellular enzyme systems may increase the demand for insulin. In others it is obviously related to antagonistic action of one or more hormones, a concept to be discussed later. In a few instances it is probably referable to an antigen-antibody reaction which inactivates insulin, as evidenced by the binding of  $I^{131}$  labelled insulin to fractions of serum globulins. Also fluorescein-tagged insulin antibody is specifically bound to beta cells in some animal species.

Diabetes has been induced by chemical agents which have a necrotizing effect upon the beta cells of the pancreas but permit the alpha cells to remain intact. One of these, *alloxan*, a pyrimidine derivative, causes permanent and severe diabetes in twenty-four to forty-eight hours after injection in all species so far studied. This form of diabetes is readily controlled by insulin, as is that following pancreatectomy. The administration of massive doses of *alloxan* to a few patients with terminal generalized carcinoma and to those with cancer of the islands of Langerhans has had no significant effect. Like *alloxan*, de-

hydroascorbic acid induces diabetes in rats and rabbits.

It is established that a protein, *glucagon*, is elaborated by pancreatic tissue other than the beta cells and has anti-insulin activity. Glucagon is presumed by many to be secreted by the alpha cells. Its elaboration according to Young is enhanced by hypoglycemia and by pituitary growth hormones. Observations of Dörner and Stahl and others indicate that alpha cells disappear in the hypophysectomized dog. The action of glucagon is short-lived and the hyperglycemia caused by it is believed by Sutherland to result from increased hepatic glycogenolysis resulting from enhanced phosphorylase activity, which in turn results from the formation of a dinucleotide in hepatic mitochondria. The action of glucagon resembles that of epinephrine; its role in the etiology of diabetes is not known. Evidence for peripheral action is not convincing.

Haist and Best observed that the insulin content of the pancreas of the normal rat could be sharply reduced either through starvation or by the administration of insulin to the normally fed animal. These procedures were not accompanied by any histological change in the pancreas. Haist and Best inferred from their studies that resting the pancreas relieved the "strain" imposed by hyperglycemia and is beneficial. The observations of Haist and Best showing a decrease in insulin content of the pancreas with rest furnish at least a partial explanation for what is termed starvation diabetes encountered in man and certain animals. It has been repeatedly observed that after starvation or a low carbohydrate diet the administration of glucose is followed temporarily by hyperglycemia of an abnormal degree and duration, often associated with glycosuria. Transient diabetes has also been observed following the surgical relief of recurrent hypoglycemia due to islet cell tumors. In this case also it appears that time is required for the islet cells to regain their normal function after prolonged relative inactivity. Wrenshall and Best find practically no insulin in the pancreas of juvenile diabetics, but glands of adult diabetics yield 25 to 30 per cent of the normal.

Diabetes in man may occur in association with a variety of diseases of the pancreas. In *hemochromatosis* it is not unusual to have associated diabetes, which some believe to be due to extensive siderosis and fibrosis of islet tissue. Mild diabetes

appears in some patients with carcinoma of the pancreas and may result from destruction of islet tissue as may also be true in the case of large pancreatic cysts. Acute hemorrhagic pancreatitis is not infrequently associated with hyperglycemia and glycosuria and permanent diabetes has been reported following recovery from pancreatitis. Trauma of the pancreas has been purported to be a cause of diabetes but this view is not established on firm grounds.

*The Pituitary.* It has long been known that diabetes mellitus is frequently found in association with acromegaly. It was therefore natural to suspect that hormones of the anterior lobe of the pituitary gland were in some way capable of disturbing carbohydrate metabolism. It remained however for Young (1937) to demonstrate that typical diabetes could be permanently established in dogs by the administration of a potent extract of the anterior lobe of the pituitary (APE) when injections were continued daily for about four weeks. Histological study of the pancreas of these animals showed lesions characteristically found in many patients with diabetes.

These important studies of Young left in doubt the question whether anterior pituitary extract exerted a direct effect upon beta cells of the islets similar to that observed following alloxan. Best, Haist and Campbell showed that the administration of a diet low in carbohydrate or the administration of insulin inhibited the diabetogenic effect of anterior pituitary extract as well as the development of histological changes in the pancreas. The basis for the development of Young's diabetes was finally established through the ingenious experiments of Lukens and Dohan. They induced "Young's diabetes" in partially pancreatectomized cats in which hydropic degeneration of beta cells persists for some months before fibrosis occurs. These investigators found that after the injections of anterior pituitary extract were discontinued and before fibrosis of islet tissue occurred the diabetes which had been established was curable. Cure could be effected in any one of three ways each of which abolished hyperglycemia: first by reduction in carbohydrate intake; second by the administration of insulin; and third by the administration of phlorizin. In other words the permanent diabetes induced by APE appears to result in the main from exhaustion of the beta cells by interference with carbohydrate utilization and long continued hyperglycemia. Young

and others believe it also acts through stimulation of glucagon. Of importance is the further observation of Lukens and Dohan who have shown that permanent diabetes with characteristic pancreatic changes can also be induced in normal cats through the maintenance of hyperglycemia for a period of ten days by the intraperitoneal injection of glucose alone.

How many fractions of anterior pituitary extract may play a part in the genesis of diabetes is not yet established. Pure growth hormone or somatotropin (STH) unquestionably has the capacity to induce permanent diabetes in dogs and cats but only in partially pancreatectomized rats. Also Cori and Bornstein have found a lipoprotein in beef pituitary which inhibits the glucokinase reaction and thus may prove to be diabetogenic. The observations of Ladd and of White concerning the onset of diabetes in children suggest that among others the growth hormone may be implicated. Thus Ladd found that 30 out of 34 children carefully studied were overgrown or overweight or both at the onset of their disease. White reports that 80 per cent of children with diabetes were definitely overweight within three months prior to the onset of their disease. Obesity was not a significant factor in White's patients. Furthermore there are numerous reports of women who have given birth to oversized infants months or years before the onset of diabetes in themselves suggesting hypersecretion of growth hormone in the mother during pregnancy. The role of ACTH in the genesis of human diabetes appears to be a minor one since a vast number of individuals have been given this hormone in amounts sufficient to induce prolonged and intense hypercorticism with only infrequent initiation of transient diabetes. However the enhancement of diabetes by ACTH is not to be questioned.

*The Adrenal Glands.* Lukens and Long first showed that extirpation of the adrenal glands ameliorated pancreatic diabetes in dogs and cats just as Houssay found a beneficial effect from hypophysectomy. With these observations the importance of the adrenal cortex in the genesis of disturbances of carbohydrate metabolism became firmly established. Ingle has been able to induce heavy glycosuria in intact rats by intensive administration of adrenal 11-oxysteroids thus further emphasizing the importance of certain adrenal steroids in their capacity to act either directly or indirectly as an anti-insulin. The increase

in glycosuria induced by 11-oxysteroids in the rat is ascribed by Stetten and Ingles to an increase in gluconeogenesis.

Himsworth points out that patients with diabetes (and probably nondiabetic persons) can be divided into insulin resistant and insulin susceptible groups. The whole implication of this generalization is not known but it is probable that either pituitary or adrenal cortical hormones or both are significantly concerned with at least some of the variations in insulin resistance. In support of this view is the fact that the diabetes occurring with acromegaly or Cushing's syndrome may be mild as judged by the degree of glycosuria and hyperglycemia but the dosage of insulin required to relieve it is reputed to be inordinately great. On the other hand in the absence of adrenal cortical hormones or in pituitary insufficiency even intense diabetes may be incredibly sensitive to minute amounts of insulin. Of interest is the observation of Vallance Owen and Lukens that an insulin inhibitor appears in the plasma of pancreatectomized cats only following four days of combined administration of growth hormone and adrenal oxysteroids. The antagonist resides in one of the globulin fractions of the plasma.

It remains to be determined how frequently excessive secretion of anterior pituitary extract or certain adrenal cortical steroids with their antagonistic behavior toward insulin activity may be of importance in the development of diabetes in man.

Whereas epinephrine is responsible for transient hyperglycemia as a result of increased glycogenolysis there is no convincing evidence suggesting that the adrenal medulla plays any part in the initiation of diabetes mellitus.

**The Thyroid Gland.** Wilder reported an incidence of 3.2 per cent of frank diabetes mellitus in a series of patients with hyperthyroidism. Diabetes occurred more than three times as often in Wilder's patients with toxic nodular goiter as in patients with exophthalmic goiter probably because of the higher incidence of nodular goiter in older age groups in whom diabetes is most prevalent. Experience dictates that overactivity of the thyroid gland should always be suspected in diabetic who are difficult to regulate and require large doses of insulin since it is well established that hyperthyroidism intensifies diabetes mellitus. However it has not been possible to establish permanent diabetes in animals by thyroid administration in contrast to the effect

of the administration of anterior pituitary extract.

**Obesity.** Among 1000 diabetics reported by Joslin 77 per cent were definitely over weight and only 8 per cent were below the normal zone. Among 252 diabetics between the ages of 51 and 60 only 2 were below normal weight prior to the onset of their disease. It is a striking fact that the correlation between obesity and diabetes occurs only in the adult group and particularly among older adults.

A majority of older obese diabetic patients lose evidence of a disturbance in carbohydrate metabolism with reduction in weight. Thus it appears that the capacity of these patients to metabolize carbohydrate tends to be impaired only in association with a food intake sufficiently in excess of normal to establish obesity. When their caloric intake is reduced to a level commensurate with the maintenance of normal weight diabetes tends to disappear.

It seems possible that the strain on the pancreas to elaborate insulin essential for oxidation of excessive carbohydrate or possibly for fat storage may lead in time to diabetes in those people with a genetic predisposition to the disease. In this connection it is of interest to note that diabetes appears in mice exhibiting hereditary obesity. Also Long and his co-workers have shown that rats rendered obese by hyperalimentation after hypothalamic injury may in time develop diabetes. From a practical standpoint the essential fact is that a relationship between obesity and diabetes is found in more than 50 per cent of persons with diabetes.

**Heredity.** A family history of diabetes can be obtained in at least 25 per cent of patients. Furthermore the incidence of diabetes in both of identical twins is approximately 70 per cent in contrast to less than 10 per cent in twins derived from separate ova. These facts in addition to studies of White and Pincus and also of Wilder indicate that the predisposition to diabetes is inherited as a Mendelian recessive which is not sex-linked. It is not known whether the genetic defect finds its expression at the hormonal level in the form of imbalances or at a more fundamental level involving defects in enzymatic processes. Be that as it may the implication of White and Pincus studies is that 100 per cent of the offspring of two diabetic parents will develop the disease—assuming the etiology of diabetes in both parents is the same.

There is a mass of evidence offered in

support of different etiologies for juvenile diabetes and the diabetes of older obese persons. To be mentioned are the acute onset in the juveniles and typically mild symptoms in the obese, the lack of fat in the liver in juvenile diabetics and classic fatty liver of the obese, the lack of insulin in the pancreas of the juvenile diabetic and its presence in the obese adult, the relative insulin sensitivity in the juveniles and comparative resistance in the obese, also the possible overactivity of the pituitary gland in juvenile diabetics as suggested by their oversize. *Nevertheless it must be remembered that persons who develop their diabetes when they are fat and elderly may have children who develop classic juvenile diabetes.* This suggests a common genetic defect but different precipitating factors in the susceptibles.

**Infection.** One of the most characteristic features of diabetes is the fact that infection may intensify the disease process and may increase enormously the demand for insulin. This is particularly true of febrile diseases but is also true of infections as trivial as the common cold. The mechanism by which activation of diabetes takes place is wholly obscure. It is not known whether infectious processes decrease the formation of insulin. They do however stimulate liberation of ACTH with increased secretion of steroids of the adrenal gland.

Diabetes often develops after an acute infectious disease but it seems improbable that the infection initiates diabetes in these patients. More probable is the explanation that these patients are latent diabetics and that infection merely brings the disease to light.

**Race.** It is a generally accepted fact that diabetes is more common among Jews than among other people. This high incidence is almost entirely limited to elderly Jews and is in all likelihood associated with a high incidence of obesity.

**Disturbances of the Nervous System.** Certain authors have emphasized that the incidence of diabetes is highest among persons whose occupations are associated with nerve strain and great responsibility but it must be recognized that a sedentary existence associated with consequent obesity in this group is probably of greater significance. The appearance of glycosuria following sudden emotional upsets or cerebral trauma is well established and was commented upon by Willis in 1679 but this is transitory in nature and is probably dependent upon sympathetic discharge of epinephrine. It seems certain that "psychic

trauma" can temporarily increase the severity of established diabetes and consequently increase insulin requirements. This becomes a point of practical importance in the management of the disease.

Whatever the etiology of diabetes the disease can be looked upon from a standpoint of practical management as a disorder in which the amount of endogenous insulin available is inadequate to meet the metabolic demands.

**Physiology.** The ability of a physician to understand the disturbances responsible for the clinical picture of diabetes mellitus and likewise his ability to treat the disease intelligently and successfully are dependent upon the knowledge of the metabolic processes involved. It is essential in gaining this background of information to contrast certain aspects of normal metabolism with the deviations encountered in diabetes.

**Carbohydrate Metabolism.** Normal carbohydrate metabolism proceeds along a number of pathways as indicated in Figure 62. A portion of the glucose from which carbohydrate metabolism originates is converted into glycogen in the liver and muscles. The remaining glucose is broken down by glycolysis to lactate and pyruvate and possibly to other 3-carbon fragments without the interposition of glycogen formation, likewise shown in Figure 67. The phosphorylation of glucose to glucose 6 phosphate is the first and essential step both for its conversion to glycogen and its degradation to smaller fragments. Pyruvate is decarboxylated to form acetyl CoA and concomitantly the reduction of diphosphopyridine nucleotide to DPNH occurs. Acetyl CoA then condenses with oxaloacetic acid to be oxidized to CO<sub>2</sub> and water via the tricarboxylic acid cycle. When carbohydrate is broken down to Acetyl CoA in excess of energy requirements two molecules of acetyl CoA condense to form acetoacetyl CoA. This enters the fatty acid spiral and on each turn condensation with additional acetyl CoA takes place lengthening the chain by two carbon atoms. Thus for example in eight turns of the spiral stearic acid is formed and ultimately fat stores at the periphery are increased.

Essentially all carbohydrate is broken down in the gut into the three hexoses glucose, fructose and galactose before being absorbed. It is generally accepted that these sugars are actively transported through the gut wall and that they do not traverse the mucosa of the small intestine by simple diffusion.

**Three Sources of Body Glucose.** Obvi-

ously the largest amount normally comes from the food a second source is liver glycogen and a third source is that derived from gluconeogenesis

Liver glycogen is derived from glucose either ingested or synthesized in the body *e.g.* from lactic or pyruvic acid elaborated to a large extent in the muscles. It turns out from studies on the rat by Stetten that the total amount of glycogen stored in the normally fed animal in twenty four hours is equivalent to only about 3 per cent of the total glucose metabolized. Hence stored glycogen appears to be almost insignificant as a source of glucose for metabolic requirements in the normal animal. This statement does not detract however from the vital importance of liver glycogen as an emergency stabilizing factor for the blood sugar level. The glycogen of the liver as well as that in the muscles derived from glucose appears as a product elaborated by a series of reactions involving the phosphorylation of glucose. These reactions are reversible except for the initial phosphorylation of glucose but it is worthy of note that the final step in the degradation of liver glycogen to glucose is accomplished by a specific phosphatase present in the liver but not in muscles consequently no free glucose is formed from muscle glycogen.

In addition to glucose absorbed from the gut and to that derived from liver by glycogen glucose may be synthesized from a variety of building blocks within the body. This synthesis is termed *gluconeogenesis*. Gluconeogenesis appears to take place primarily in the liver from 2 to 3 carbon fragments which appear in the course of the metabolism of protein fat and carbohydrate. Included in these are certain amino acids from protein (*e.g.* alanine) glycerol from fat lactate and pyruvate from glucose and probably many other

substances. The amount of glucose made available by gluconeogenesis in the normal rat according to Stetten is approximately ten times that derived from glycogen. The importance of this process in body economy is apparent.

*The Normal Fate of Glucose in the Body*  
As stated before only about 3 per cent of the glucose metabolized by the normal rat is to be accounted for by glycogen formation. Of the remaining 97 per cent Stetten has shown that 30 per cent i.e. ten times as much as goes to glycogen is converted to fatty acids after breakdown to acetyl coenzyme A. The portion of glucose not converted to glycogen or fatty acid (about 70 per cent of the total) after being split to lactate pyruvate and other 3-carbon fragments is either oxidized (chiefly in the muscles) by means of the tricarboxylic acid cycle to carbon dioxide and water or is made available for amino acid and ultimately protein synthesis.

*Carbohydrate Metabolism in Diabetes*  
The major defect in carbohydrate metabolism in diabetes mellitus is due to a decrease in the utilization of glucose. It seems probable that gluconeogenesis from protein is significantly increased by 11-oxysteroids of adrenal origin. Studies of Stetten have demonstrated conclusively that the amount of extra glucose found (gluconeogenesis) in phlorizin diabetes in which the loss of sugar is dependent solely upon a renal lesion is just as great as it is in the truly diabetic animal (alloxan poisoned) in which the loss of glucose is due to a disturbance in the insulin mechanism. In other words there is no more "overproduction" of glucose in alloxan diabetes than in renal glycosuria induced with phlorizin. It appears at the present time that "under utilization" of glucose results from the summation of three defects (*vide* Figs 67 and 68) first a decrease in oxidation of glucose and a decrease in its utilization in

FIG 67 Diagram of normal carbohydrate metabolism. (Thickness of arrows indicates possible magnitude of the reactions)

FIG 68 Diagram of carbohydrate metabolism in diabetes mellitus. (Thickness of arrows indicates possible magnitude of the reactions)

amino acid and protein synthesis and some increase in gluconeogenesis second a decrease in fatty acid formation from glucose to about one twentieth of the normal thus making this nonmetabolized glucose also available for urinary excretion and third a decrease in glycogen storage in the liver and muscles which however contributes only slightly to the total amount of glucose excreted over any considerable period of time

It must be emphasized that whereas the capacity to oxidize glucose and the ability to convert glucose to glycogen may be seriously impaired in diabetes these functions contrary to earlier thought are not completely interrupted. It may well be that the oxidation of glucose which does continue in the brain and probably in other tissues in diabetes is independent of insulin action and is akin to that in unicellular organisms which utilize carbohydrate without a pancreas. This is also suggested by the fact that the depancreatized animal is capable of increasing the utilization of glucose in response to muscular work. This appears to result from an increase in the transport of glucose into cells similar to that induced by insulin.

Glucose may be oxidized after phosphorylation by a pathway known as the "hexose monophosphate shunt." This pentose pathway does not follow the steps of the conventional Embden-Meyerhof anaerobic glycolysis. Its importance has not been entirely clarified but it appears to be involved at least in the formation of ribose for nucleic acid synthesis and for the elaboration of TPNH. Activity of the pentose pathway is reduced in severe diabetes.

**Insulin.** This hormone of the islands of Langerhans is a single protein the biological activity of which is dependent upon the integrity of the disulfide bridges between cysteine residues in adjacent polypeptide chains. The monomeric insulin molecule has a molecular weight of 5734 and it exists in micelles of molecular weight of about 48,000.

The mechanism of action of insulin is not firmly established and two views continue to prevail. Levine and Goldstein have presented impressive evidence favoring the idea that insulin acts by enhancing the penetration of glucose into the cell and that in the diabetic animal glucose fails to be utilized because it is incapable of entering the cells where it is normally phosphorylated and then utilized. Cori has shown that this effect of insulin is not specific for

hexoses but applies also to certain pentoses. Cori and Cori maintain that the defect in diabetes results from an inhibition of phosphorylation of glucose to glucose 6-phosphate by a factor in the pituitary gland. This may be growth hormone. They believe that insulin counteracts this pituitary inhibition of glucokinase. The utilization of glucose appears to be dependent upon a binding of insulin to the muscle. Chaikoff has shown as has Miller that *in vitro* or *in vivo* fructose in contrast to glucose is utilized normally by tissues of the diabetic organism. Levine suggests that this may be cause insulin is not needed for the penetration of fructose into cells. With the alternative hypothesis it would be assumed that the fructokinase reaction is intact whereas the glucokinase reaction is disturbed in the diabetic. The balance of evidence at present favors the view of Levine. In the absence of insulin there is some reduction in oxidative phosphorylation (in the cat) and also an increase in glucose 6-phosphatase in the liver. It seems possible that these changes are secondary to the failure of glucose penetration into cells rather than being specific defects.

Regardless of the mechanism of action of insulin its overall effects are readily demonstrable in the diabetic animal. The reactions which appear to benefit at least indirectly from the administration of insulin are indicated in Figure 69. Here it will be seen that insulin enhances the normal breakdown of glucose to pyruvate which is ultimately oxidized to carbon dioxide and water and which also serves as a stepping stone in the conversion of glucose to fatty acids. Furthermore insulin appears to aid indirectly in the synthesis of certain amino acids and their incorporation into body protein. By virtue of increasing glucose oxidation insulin decreases gluconeogenesis in the diabetic and thereby decreases the loss of nitrogen from the body. The increase in glucose utilization following insulin injection similarly decreases the need for mobilization and oxidation of fat in the diabetic. It appears that both fat storage and protein synthesis are dependent upon the oxidation of glucose. In the absence of insulin protein synthesis induced by growth hormone is minimal. Insulin also greatly increases glycogen storage in the liver and to a less extent in striated muscle in diabetes. It actually decreases glycogen storage in cardiac muscle and kidney.

In the normal animal insulin tends to decrease glycogen storage in the liver. This

appears to result from an increase in glycogen storage or glucose utilization in striated muscle which results in a decrease in the blood sugar level. This in turn results in glycolysis in the liver to reestablish the level. The action of insulin at the periphery was demonstrated by its augmentation of the arteriovenous difference in blood sugar in an extremity in the early studies of Cori and Cori.

A number of types of insulin are now available for clinical use. All are derived from either hog or beef pancreas and all have the same basic actions on carbohydrate metabolism. The preparations of insulin in use include regular insulin, crystalline insulin, globin insulin, protamine zinc insulin, NPH insulin, and zinc insulin mixtures. The chief difference in these modifications of insulin is in the time of action. Thus in the fasting diabetic, regular and crystalline insulin exert their effect on blood sugar for about six to eight hours, with a peak effect at about three to four hours. Globin insulin is active for about twenty to twenty-four hours with maximal action at eight hours. NPH or isophane insulin, about equivalent to a 2:1 mixture of regular and protamine zinc insulin, exerts action for twenty-four to twenty-eight hours with maximal action also at about eight hours. Protamine zinc insulin (PZI) may have activity persisting in excess of thirty hours with a peak effect between twelve and twenty-four hours. The Danish zinc and insulin suspensions (IZS) vary in their duration of action from eighteen to ninety-six hours. Commercial lente insulin is an admixture of semilente and ultralente zinc insulins and has a time action curve like that of isophane insulin. The duration of action of any insulin varies in different persons depending on rates of absorption and other unknown factors.

The adrenal glands exert important influences on carbohydrate metabolism. Epinephrine, when administered to the well-nourished animal, characteristically raises the blood sugar as a result of increasing the breakdown of liver glycogen to glucose. When liver glycogen stores are depleted, epinephrine appears to decrease muscle glycogen similarly with the liberation of lactic acid, which is transported to the liver and resynthesized to glycogen or glucose. The adrenal cortex, as mentioned under Etiology, is capable of causing profound changes in carbohydrate metabolism. The 11 oxysteroids induce glycosuria and an increase in nitrogen excretion in normal animals, and they intensify already-existing

diabetes. The mechanism of action of these steroids has not been established, but they are known to inhibit the synthesis of certain proteins and enhance strikingly gluconeogenesis from proteins. Cori believes they enhance inhibition of phosphorylation of glucose by pituitary hormones.

As stated above, growth hormone particularly in association with insulin is effective in increasing nitrogen storage by augmenting protein synthesis. It is also diabetogenic, as discussed elsewhere.

The effect of the thyroid hormones, as mentioned before, intensifies glycosuria in the diabetic and causes transient glycosuria in normal persons. This effect appears to result primarily from the fact that thyroid substance increases the rate of absorption of glucose so that the threshold for excretion is readily exceeded. It also increases glycogen breakdown.

**Blood Sugar.** The concentration of glucose in the blood at any given time is the resultant of forces tending to remove glucose to the tissues for utilization and forces leading to the synthesis of glucose or to an increase in its flow to the blood stream, as indicated by the arrows in Figure 67. The most important factor quantitatively determining the height of the blood glucose level is obviously the glucose absorbed from the gut. The normal fasting blood sugar level is 80 to 120 mg per 100 ml, of which about 20 mg is not glucose and is accounted for by other reducing substances. After the ingestion of a liberal amount of carbohydrate, the level rises normally to about 150 mg per 100 ml in thirty to sixty minutes and returns approximately to the fasting level in the course of two hours.

In order to maintain the normal fasting blood sugar level, the pancreas must liberate the proper amount of insulin. This control mechanism is generally believed to be regulated by vagal stimulation and the concentration of glucose in the blood. Thus when the blood sugar level begins to rise

FIG. 69 Diagram of processes apparently enhanced by insulin in the diabetic.

the islet cells are stimulated to elaborate more insulin. When the level tends to fall insulin formation is diminished and the liberation of epinephrine and glucagon is believed to stimulate glycogenolysis in the liver which restores the blood sugar level. The part played by anterior pituitary extract and certain adrenal cortical steroids in the maintenance of the normal blood sugar level is undoubtedly also of great importance.

When the blood sugar level is in excess of about 170 mg per 100 ml glycosuria appears. Under these conditions the renal tubules are unable to reabsorb all the glucose present in glomerular filtrate. In a number of older diabetics the normal renal threshold is raised and the urine remains sugar free even when the blood glucose level is greater than 300 mg per 100 ml. Possibly this elevation of threshold can in some way be correlated with capillary glomerulosclerosis which is common in this group of patients and results from a decrease in filtration and in some instances an increase in tubular reabsorption.

**Fat Metabolism.** The storage of neutral fat occurs chiefly in the subcutaneous depots. This fat is derived normally from that ingested and from fatty acids derived from glucose as described under Carbohydrate Metabolism. The liver which is intimately involved in fat metabolism as well as in carbohydrate metabolism normally contains 2 to 4 per cent of fat. Concentration of fat in excess of 10 per cent may appear in the liver however under a great array of circumstances including obesity, pregnancy, starvation, phlorizin diabetes and in elderly obese but not in juvenile diabetics. Diets containing large amounts of fat, biotin or cystine or diets deficient in methionine, choline or betaine also give rise to an increase in the fat content of the liver as do chloroform and other liver poisons.

The mechanisms by which fat is mobilized from the peripheral tissues to the liver are not understood. However a substance in the anterior pituitary, adipokin, is capable of inducing this migration of fat. The importance of this pituitary stimulus for fat mobilization in the variety of conditions under which liver fat is increased is not known and the way in which it affects mobilization is also obscure.

The total lipid concentration of the normal plasma is from 500 to 600 mg per 100 ml. Approximately one half of this is in the form of neutral fat and fatty acid

and the remainder is composed of cholesterol and its esters and phospholipid. When the rate of mobilization is greatly increased as in uncontrolled diabetes complicated with severe ketosis the concentration of blood lipid may be enormously increased. In one of the writer's patients it reached 25 per cent. Unesterified fatty acids (UFA) are present in normal plasma in minute amounts but have an enormous turnover rate. UFA decrease normally in plasma with administration of glucose or insulin and increase in diabetes particularly with impending ketosis. Gordon has shown that epinephrine *in vitro* increases UFA release from adipose tissue and insulin *in vitro* depresses this process. The full implication of these observations is not yet apparent.

The oxidation of fat begins in the liver (except for a small increment in the kidneys and other tissues) and proceeds by stepwise degradation down the fatty acid spiral the length of the molecule being shortened by two carbon atoms on each turn with the formation of one molecule of acetyl CoA perhaps by a process the reverse of that for fatty acid synthesis outlined in the Section on Carbohydrate Metabolism. In the complete degradation of fatty acids the acetyl CoA formed is oxidized to CO and water as mentioned above. In the severe diabetic there does not appear to be any difficulty with fat degradation which is actually greatly increased. On the other hand fatty acid synthesis comes almost to a standstill. The large quantities of acetyl CoA not oxidized are diverted into the synthesis of ketone acids. This diversion has been variously ascribed to a diminished supply of reduced pyridine nucleotides or oxaloacetate resulting from failure of carbohydrate metabolism. Convincing evidence for either of these hypotheses is lacking.

Ketone bodies are rapidly transported from the liver to other tissues notably the muscles where they serve both in the normal and the diabetic as a source of energy and are ultimately oxidized to carbon dioxide and water. This utilization is so complete that under normal conditions only traces of ketone bodies appear in the blood and urine.

**Ketosis and Acidosis.** In the course of uncontrolled diabetes glycosuria increases in intensity and is accompanied by a large rise in the urinary excretion of nitrogen due to an increase in gluconeogenesis (the gluconeogenesis appears to be at least in part due to the inability to store protein normally in the absence of insulin). Soon

there follows a great increase in the catabolism of fat. The rate of breakdown of fat to ketone bodies in itself a normal process is far in excess of the rate at which acetoacetic and beta-hydroxybutyric acids can be utilized by muscles and other tissues. Consequently the ketone bodies increase in the blood at times reaching levels of 200 mg or more per 100 ml. This ketonemia is associated with urinary ketone body excretion which often exceeds 60 gm a day.

Ketosis develops also in other disorders in which adequate amounts of glucose are not available as in the course of starvation or in phlorizin poisoning. It also appears when the diet contains fat in excess of about 4 gm for each gram of glucose available as such or that derived from protein (about 58 per cent). It seems certain that glucose oxidation is essential both for the storage of fat and the synthesis of body protein. When oxidation of glucose is sharply reduced in diabetes as a result of an inadequate supply of insulin or in starvation because of an inadequate supply of glucose then mobilization and breakdown of fat with varying degrees of ketone formation transpire by the routes indicated above. Also in the absence of glucose oxidation negative nitrogen balance ensues because of failure of protein synthesis and because of gluconeogenesis from amino acids.

One of the many unresolved problems concerning the mechanism of ketosis is the unpredictability with which it appears. For example one of two wholly similar diabetics may in the course of twenty-four hours after the withdrawal of insulin exhibit serious ketosis in association with heavy glycosuria. The other under apparently identical circumstances and with the same glycosuria will develop essentially no ketonemia or ketonuria despite persisting glycosuria and nitrogen loss. It may be stated as a generalization that juvenile (insulin deficient) diabetics are prone to severe ketosis and that obese elderly (insulin resistant) diabetics are less subject to ketosis but there are exceptions.

Because two of the three ketone bodies are acids their continued elaboration leads to disturbances of acid base equilibrium. Their accumulation in the blood plasma reduces the bicarbonate content and ultimately causes severe acidosis. Both acetoacetic and beta-hydroxybutyric acids are relatively strong acids and whereas they are in part excreted as such a much larger part is excreted in association with cations. Some of this is furnished by the ammonia

mechanism but there is also serious depletion of fixed cations including sodium, potassium and calcium as acidosis progresses. Moreover Atchley, Richards and the writer showed that the loss of fixed cations in severe diabetes actually begins coincidentally with the development of heavy glycosuria and before ketosis occurs. This loss of cations is associated with the loss of intracellular and extracellular water as well as with the breakdown of cells as judged by nitrogen loss. The general problem of acidosis is dealt with elsewhere in this volume.

The accumulation of beta-hydroxybutyric acid in the body is relatively harmless except for its effect upon acid base equilibrium. On the other hand acetoacetic acid and acetone are distinctly toxic and their accumulation depresses the central nervous system. It seems probable that a considerable part of the picture of diabetic coma may properly be ascribed to intoxication by these ketone bodies. Kety has demonstrated a 40 per cent reduction in cerebral utilization of oxygen in diabetic coma and ascribes it in part to the acidosis and more significantly to the ketosis and possibly other factors.

**Caloric Requirements.** Age, sex, surface area, physical activity, state of nutrition, fever, thyroid activity and probably many other factors influence energy requirements. Consequently to attempt to set down the number of calories required by any person to maintain a given weight is not in most instances helpful. In general sedentary adults require in the neighborhood of 30 calories per kilogram; the requirements of children are greater and those of the aged tend to be less. The deviations from these generalizations are however great and the only practical procedure to be followed in establishing caloric requirements is that of trial and error using body weight as an index. It should be noted that the caloric requirements of the diabetic do not differ from those of the normal.

The protein requirements are also variable and are governed more or less by the same factors which influence the total caloric needs. The amount of carbohydrate in the diet however has a significant effect upon the protein intake essential to maintain nitrogen equilibrium. An intake of 100 to 150 gm of carbohydrate daily cuts down nitrogen loss in starvation appreciably. With increase in carbohydrate beyond this amount Butler has shown that additional nitrogen-sparing action of car

bohydrate is inappreciable at least in normal young adults

**Morbid Anatomy** The commonest histological lesions in diabetes mellitus are found in the pancreas. It is interesting to note however that in the meticulous studies of postmortem material by Cecil and others more than 10 per cent of the cases failed to reveal any pancreatic lesions. In the cases in which changes are encountered in the pancreas no one distinctive lesion is uniformly present in the islets. In some cases there appears to be a reduction in the total number of islets without other lesions demonstrable. In others hydropic degeneration of the beta cells has been noted. The most frequently encountered lesions are hyaline degeneration and sclerosis of the islands of Langerhans. The lesions observed may be secondary to an abnormality of carbohydrate metabolism originating outside the pancreas as in "Young's diabetes" or as in cats maintained hyperglycemic by the prolonged administration of glucose intraperitoneally. Local destructive disease of the pancreas including diffuse pancreatitis, extensive tumors and large cysts may be the cause of diabetes. Also hemochromatosis with intensive infiltration of the pancreas with hemosiderin and ceroid is often associated with diabetes.

The kidney is frequently the site of a variety of lesions in diabetes mellitus. These include pyelonephritis, capillary glomerulosclerosis and necrotizing papillitis discussed in the section on Complications.

Sherlock has demonstrated by liver biopsy striking increase in deposition of fat in the older relatively resistant obese diabetics in contrast to juvenile diabetics in whom there is no increase in liver fat.

Arteriosclerotic lesions are extraordinarily prevalent in patients with diabetes. This is discussed more fully in the section on Complications.

**Clinical Symptoms and Signs** In children and young adults an abrupt onset or one which can be dated within a two month period is encountered in about 65 per cent of patients according to Joslin. In the older age groups the onset is usually so insidious that it cannot be established. Among these patients the disease is often discovered only in the course of routine examination of the urine because if symptoms do exist they are not sufficiently severe to cause the patient to seek medical attention. Other patients more than forty years old first see the physician when a com-

plication arises suggesting that diabetes may have been present but unrecognized for years.

The most common and characteristic symptom of diabetes and the one from which it derives its name is *polyuria*. Patients not infrequently pass large amounts of urine day and night and the volume is often in excess of 3 or 4 liters. Inordinate thirst *polydipsia* may torment the patient and lead him to seek medical advice. Less frequent but not uncommon is a striking increase in appetite *polyphagia*. This is particularly true in children who are brought to the physician by parents because despite a great improvement in appetite the children fail to gain weight or strength. Many patients complain of loss of weight or loss of strength or both losses of 20 to 40 pounds in the course of a few weeks or months being not unusual. The symptoms of *polyuria*, *polydipsia*, *polyphagia*, loss of weight and loss of strength are generally associated with the more acute and severe forms of the disease. Among older patients there may be an abnormal tendency to postprandial *drowsiness* not related to ketosis; at times there are vague aches in the legs or other symptoms as already mentioned referable to some complication.

In uncomplicated diabetes there are but few physical signs which alone would lead one to suspect the disease. Possibly marked emaciation and dryness of the skin and mucous membranes without obvious cause might be considered evidence. In uncontrolled diabetes in children hepatomegaly is common and is at times associated with splenomegaly.

The characteristic feature of the urine in diabetes is obviously the presence of glucose. The concentration of sugar may vary from mere traces to as much as 10 per cent and the total excreted in twenty four hours varies from insignificant amounts to several hundred grams. In general the amounts excreted are indicative of the intensity of the disorder at the time. In the presence of ketosis the urine usually contains large quantities of ketone bodies which can be detected by the nitroprusside and ferric chloride reactions. Proteinuria and numerous casts are often present in ketosis. The blood sugar level may be normal or markedly elevated depending upon the circumstances of the test and the severity of the disease. In severe uncontrolled diabetes it may exceed concentrations of 1000 mg per 100 ml. It has already been mentioned that blood lipids are often increased in

diabetes particularly when ketosis is present. When emaciation is marked hypoproteinemia may be extreme and there is a sharp reduction in the serum albumin fraction with some increase in alpha  $\Pi$  globulins. It is rare at the present time to find cases which have reached this stage of protein depletion. In uncomplicated diabetes there is no reduction in the erythrocyte count except in the presence of marked malnutrition when mild secondary anemia may be present. With severe dehydration in ketosis hemoconcentration may be moderate. The leukocyte count is normal except in severe ketosis and acidosis when it usually rises to 20 000 or 30 000 per cu mm. The sedimentation rate of the red cells is essentially normal except in the presence of acidosis or complications of infectious origin.

**Complications.** With the increasing span of life of patients with diabetes complications may be expected to increase consequently they deserve particular consideration in management of the disease.

**Acidosis and Coma.** In days before the advent of insulin approximately 50 per cent of diabetics died from these complications. Today death in coma is a rare occurrence in well organized clinics and a case terminating fatally deserves critical review to determine the reasons for coma and for failure of therapy. Whereas deaths from acidosis have become a rare occurrence it must be emphasized that any diabetic may succumb in two or three days if control of his disease is not rigidly exercised. Ketosis with its sequelae, acidosis and coma is usually precipitated by one of the following disorders: (1) infections of the respiratory, genitourinary or gastrointestinal tract or pyogenic infections; (2) surgical procedures or trauma; (3) gastrointestinal disturbances with reduction of food intake or vomiting. The commonest contributing factor to ketosis in these conditions is the ill advised reduction or omission of insulin by the patient because of a decrease in food intake. In reality all these disturbances effect an increase in the insulin requirement! It should be emphasized that in many instances emotional disturbances are the basis for increases in glycosuria, ketonuria, "digestive" disturbances and the subconscious or conscious rationalization for the withdrawal of insulin.

The development of acidosis is usually associated with symptoms of increasing weakness, weariness, dull headache and general malaise. The onset may be abrupt

or insidious. Insatiable thirst soon becomes a prominent feature and as acidosis progresses hyperpnea or the "air hunger" of Kussmaul appears with little if any subjective distress. Epigastric aching pain adds to the discomfort of the patient and is associated with increasing nausea and vomiting and persistent thirst. The abdominal symptoms in association with the striking leukocytosis usually present in severe ketosis often arouse suspicion of acute inflammation in the peritoneal cavity. The patient becomes more and more listless and may sink into coma quietly and die or coma may be preceded by a period of great restlessness, irritability and confusion.

On physical examination the patient in severe diabetic acidosis shows marked dehydration of the mucous membranes and loss of turgor of the skin. The eyes are sunken, the lips and tongue red and parched and the cheeks either flushed or else very pale. The breath has the characteristic fruity odor of acetone and hyperpnea is apparent. These signs are accompanied by a rapid feeble pulse, a temperature which may either be elevated or subnormal and by arterial hypotension. The blood pressure may fall to 60 to 70 mm of mercury as coma deepens and anuria supervenes, together with progression of peripheral circulatory collapse. In older patients this state of shock if allowed to continue gives rise to myocardial insufficiency probably because of decreased blood flow in the coronary arteries.

The severity of diabetic acidosis may be arbitrarily but conveniently classified in relation to the bicarbonate combining power of the blood serum. When the serum carbon dioxide content falls below 25 volumes per 100 ml severe acidosis may be said to be present. A carbon dioxide of 25 to 40 volumes per 100 ml may be considered indicative of moderately severe acidosis and values between 40 and 50 volumes are consistent with mild acidosis. This is a purely clinical classification and is not correlated with actual shift of the pH from normal which is obviously more significant than is the CO<sub>2</sub> level. Deep coma due to ketosis and acidosis rarely if ever develops with a blood carbon dioxide above 25 volumes per 100 ml. When the carbon dioxide is higher it is particularly important to exclude other causes of coma. The other typical blood and urine findings have been described. It should be added for emphasis that loss of bicarbonate and also of chloride results from their replacement by

ketone acids and from a loss of sodium from the blood and intercellular fluids by renal excretion. In the presence of renal failure occurring in the course of peripheral circulatory collapse ketone bodies may virtually disappear from the urine. Failure to appreciate this fact may result in failure to recognize severe diabetic acidosis. In these patients large quantities of acetone can be demonstrated in the blood plasma with the simple nitroprusside reaction. Patients exhibiting renal insufficiency may also have retention of nonprotein nitrogen in excess of 200 mg per 100 ml.

**Kidneys.** With the lengthening of the life span of diabetics renal complications assume a progressively more frequent and serious role. The commonest namely pyelonephritis may be wholly asymptomatic and recognized only by recurrent or constant mild proteinuria and pyuria. It may however be associated with typical acute symptoms. With progressive disease hypertension and uremia often supervene.

The most characteristic renal complication of diabetes is *capillary glomerulosclerosis* in which hyaline globules appear in and between the capillary loops. When the process is marked it is often associated with the *Kimmelstiel-Wilson nephrotic syndrome* characterized by proteinuria, hypalbuminemia with increase in alpha 2 globulin, edema and arterial hypertension. In the milder cases there may be only proteinuria with or without hypertension. This disorder occurs infrequently in patients whose diabetes is of less than five years duration and appears to be frequent when diabetic control has been poor. Its incidence varies with the criteria set by individual pathologists but is of the order of 20 per cent in many autopsy series. The lesion is best diagnosed in life by renal biopsy—this is of particular importance in its differentiation from low grade pyelonephritis. The management of the *Kimmelstiel-Wilson syndrome* is that of chronic nephritis.

*Capillary glomerulosclerosis* is often associated with diabetic retinopathy and neuropathy these together are known as the diabetic triopathy which some authorities believe to represent a different form of diabetes. The evidence for this view is not convincing. Of interest is the fact that as renal failure progresses usually slowly in capillary glomerulosclerosis insulin requirements decrease perhaps because of a decline in renal insulinase activity. *Necrotizing papillitis* should be suspected in diabetics exhibiting renal shut down in asso-

ciation with severe acidosis particularly with circulatory collapse or in sepsis. This disorder is encountered most frequently with diabetes but it occurs also without it.

**Arteriosclerosis.** Because about 50 per cent of diabetes occurs in the fifth and sixth decades it is to be expected that arteriosclerosis in its various forms will appear concurrently. It seems however that the two disorders are more intimately related since 50 per cent of White children who had diabetes for more than fifteen years had calcification of leg vessels. How much metabolic factors such as long-continued hyperglycemia and hypercholesterolemia contribute to the arteriosclerotic process is not known. It is of interest that Mendowitz has demonstrated decreases in digital blood flow in young diabetics and that this change is largely independent of intensity and duration of the diabetes and the age of onset. Lax and Feinberg have demonstrated in many diabetic children changes in the pulse wave characteristic of arteriosclerosis or hypertension. Furthermore 11 of 21 children of diabetic parents showed these changes although they were not diabetic themselves at that time. This suggests the possibility that the vascular lesions may be at least in part unrelated to their genesis to the intensity and duration of overt disturbances in carbohydrate metabolism. Decrease in circulation in the legs gives rise to trophic ulcers in the sole of the feet and also serves as a basis for infection and for gangrene one of the most serious complications of diabetes. It is generally believed that these complications appear most frequently in neglected diabetes of long standing. It seems possible that neglect of the feet, dermatophytosis and secondary infection in patients with compromised circulation are of greater importance. Angina pectoris and cardiac infarction are extremely common in older diabetics. This is of importance in relation to the management of older patients with insulin.

**Eyes.** Retinitis may occur in diabetics with or without hypertensive vascular disease and may appear as early as the second decade of life. This disorder is ten times as frequent in patients who have had their disease for fifteen years as it is in patients in whom diabetes has been known only one year. It is generally believed that the diabetic retinitis is most apt to develop in patients with poorly controlled diabetes or in those who have been given a diet high in fat and low in carbohydrate. The most characteristic lesion is

aneurysmal dilatation of the finer blood vessels often simulating punctate hemorrhages. Hemorrhages are also common and frequently occur in association with waxy and cotton wool exudates. Later proliferating retinopathy and advanced arteriosclerosis are found.

Cataracts may develop in young diabetics but their incidence is extremely low. Senile cataract is common in older diabetic patients but perhaps no more so than in nondiabetic persons of the same age group.

**Nervous System.** Rundles has reported 125 cases of diabetic neuropathy among 3000 diabetics. These include peripheral neuritis with motor and sensory changes most frequently involving the legs as well as lesions of spinal nerve roots and autonomic disturbances involving the bladder and vasomotor apparatus. There are no clinical signs which with any regularity serve to distinguish diabetic neuritis from neuritis due to other causes with the exception of miserable pain which is a particularly prominent feature of diabetic neuritis. Associated with the diabetic neuropathies there is often an increase in spinal fluid protein which may reach 200 mg per 100 ml.

The basis for neurological lesions is not established. It seems unlikely that vitamin B<sub>1</sub> or B<sub>2</sub> deficiency to which it has been ascribed plays any part. Probably some of the diabetic neuropathies result from "ischemic neuritis due to sclerosis of the vasa nervorum. In the opinion of Rundles the neuropathies are caused by other metabolic disturbances which appear in the course of poorly controlled diabetes. In support of this view is the fact that striking improvement frequently follows a period of adequate regulation of the disease. Probably multiple factors play a part in the genesis of the diabetic neuropathies. Mirsky has reported that diabetics regardless of duration of their disease, intensity or age at onset exhibit a diminution in vibratory sense equivalent to that in nondiabetics two decades older. This suggests that neurological lesions like vascular lesions may not be correlated with the disturbances in carbohydrate metabolism. Diabetic neuropathies are encountered from the first decade on. In Rundles series however about 17 per cent appeared in the sixth decade alone.

Diabetics are particularly susceptible to cerebral infections with *mucormycosis*. The syndrome including uncontrolled diabetes mellitus associated with ophthalmoplegias, signs of meningoencephalitis and often

sinusitis should arouse suspicion of this infection which is usually but not invariably fatal.

**Skin.** Furuncles and carbuncles are sufficiently frequent in patients with diabetes to make examination of the urine for glucose mandatory in any person suffering from these pyogenic infections. Pruritus of a generalized nature is an occasional complication of diabetes but pruritus is much more commonly limited to the vulva. Pruritus vulvae is frequently associated with infection due to *Monilia albicans*.

Numerous observers have commented on the presence of xanthochromia in diabetes. Rabinowitch, Ralli and others showed this to be the result of an increase in the circulating carotene which occurs because of an apparent decrease in the capacity of the liver of the diabetic to convert carotene into vitamin A. Xanthochromia is not to be confused with xanthoma diabeticorum, a relatively rare disorder characterized by nodules commonly on the elbows, ulnar surfaces of the forearms and knees and usually associated with hypercholesterolemia.

**Tuberculosis.** The incidence of pulmonary tuberculosis is about four times higher among diabetics than among nondiabetics. The two diseases occur together with sufficient frequency so that all diabetics should have roentgen ray study of the chest as part of their routine examination.

**Course and Prognosis.** At the present time diabetes mellitus must be looked upon as a chronic and incurable disease. There is a tendency for it to progress in intensity with time but there are many exceptions to this generalization. The fluctuations in intensity of the disease in any patient have already been commented upon. Richardson found that in a group of 55 patients followed for more than five years the insulin requirement increased in 21 and actually decreased in 10. In a group of 45 patients who did not require insulin for regulation 21 were still able to remain sugar free without insulin after five years of observation.

The average duration of life in diabetics in all age groups according to Joslin has increased from 4.9 years in pre-insulin days to about 13 years at the present time. The most striking increase in the anticipated span of life is in the young. For example in an analysis of Joslin's material it appears that the life expectancy of a child of ten years with diabetes is forty years in contrast with the normal expectancy of fifty-seven years. At sixty the anticipated duration of life is ten years in contrast to the

normal of sixteen years (Metropolitan Life Insurance Company)

The actual cure of diabetes mellitus is probably a rare occurrence. In the obese as mentioned under Etiology it is not unusual to find a reversion to normal carbohydrate metabolism with a return to a more normal weight. In these persons diabetes should be considered "latent" rather than cured because a return of obesity is associated with a return of overt diabetes. In hyperthyroidism likewise relief of this disorder may cause mild diabetes to become latent. With growths of the adrenal glands in which diabetes results from the elaboration of antinsulin, e.g. Cushing's syndrome, diabetes may be relieved by removal of an adrenal cortical tumor.

**Classification** Patients are usually classified as having mild, moderately severe or severe diabetes and yet the basis for such classification is wholly arbitrary and quantitatively ill defined. There would be general agreement that a diabetic requiring only moderate restriction of his diet for adequate control of his disease could be termed as having mild diabetes. Furthermore if in the absence of insulin therapy heavy glycosuria, loss of weight and acidosis tend to develop, all would agree that the disease is severe.

The dosage of insulin required for the regulation of diabetes also serves at times as a general guide for classification. However it has been indicated elsewhere that certain endocrine and other factors determine insulin requirements, hence exceptions to the use of insulin dosage as the grounds for classification have to be made. For example, a girl with Addison's disease and diabetes who excreted 60 to 80 gm of glucose daily without insulin could scarcely be classified as having mild diabetes merely because in these circumstances her insulin requirement was only 4 to 6 units a day. Adding still further to the difficulty of definite classification of diabetes is the fact that the individual patient may fluctuate from one category to another. Thus mild diabetes may in the course of an acute infection become severe only to revert to a milder form with subsidence of infection.

**Diagnosis** The diagnosis of diabetes mellitus affords no difficulty when polyuria, polydipsia and polyphagia are associated with an elevation of the fasting blood sugar level and with glycosuria. Even in the absence of symptoms glycosuria related to the ingestion of carbohydrate and a post absorptive blood sugar concentration in ex-

cess of 120 mg per 100 ml constitute an adequate basis for the diagnosis. The presence of glycosuria is however not essential for the diagnosis because the renal threshold may be significantly elevated in certain older diabetics. In this group the fasting blood sugar may be as high as 200 mg per 100 ml and glycosuria may appear only after meals if the blood sugar exceeds levels as high as 300 mg per 100 ml.

Diabetes mellitus should be suspected in any person who exhibits glycosuria in relation to food intake on an unrestricted diet or whose venous blood sugar level rises above 170 mg per 100 ml at any time. In these patients the form of the blood sugar curve following either a carbohydrate rich meal (containing potato three slices of bread, a sugar containing dessert and sugar in coffee) or a glucose tolerance test may prove helpful in establishing the diagnosis of latent diabetes. The glucose tolerance test may be carried out by determining the blood sugar level before and after the oral administration of 1 to 1.75 gm of glucose per kg of body weight in the fasting state. The blood sugar should be determined before and one and two hours after the administration of glucose and urine collected at these times should be tested for sugar. Normally the blood sugar does not rise above about 150 mg per 100 ml in one half to one hour after the ingestion of the glucose and returns to a normal level in two hours and the urine remains sugar free. If higher levels are reached or if the blood sugar does not return to normal in two hours diabetes should be suspected. Conn suggests that 11 oxysteroids given in conjunction with glucose tolerance tests unmask otherwise undetectable diabetes.

Beaser has pointed out that cognizance should be taken of the presence of "latent" diabetes characterized clinically only by a diabetic glucose tolerance curve and possibly transient glycosuria. When these occur particularly in persons with a family history of diabetes, the avoidance of obesity and the restriction of dietary sugar may prevent the establishment of overt diabetes.

The interpretation of the glucose tolerance test is to a great extent dependent upon the conditions under which it is carried out. The state of nutrition and the nature of the diet preceding the test are of prime importance. This is graphically demonstrated in Figure 70. Thus the curve characteristic of diabetes occurs in patients with undernutrition or in those who have maintained a diet low in carbohydrates.

whereas in the same person after the liberal ingestion of carbohydrate for a few days prior to the test normal responses are evoked. As has been mentioned before this diabetic type of response following undernutrition or the administration of insulin to the normal is characteristic of "starvation diabetes." Likewise as stated before this temporary decrease in glucose tolerance may in part result from "rest" of islet tissue with a decrease in the elaboration of insulin. It is well established also that the effectiveness of insulin in man and animals is in general reduced by starvation or by low carbohydrate diets and on the other hand it is increased by the liberal ingestion of carbohydrate and by hyperglycemia. It is therefore important to bear in mind that glucose tolerance curves typical of diabetes may signify undernutrition or carbohydrate starvation and not necessarily the presence of diabetes mellitus.

Errors in the diagnosis of diabetes may occur from faulty appraisal of normal or low blood sugar values obtained after strenuous exercise. If a person either normal or diabetic exercises after the ingestion of carbohydrate an appreciable reduction in blood sugar occurs in association with an increase in utilization of glucose.

Transient hyperglycemia and glycosuria occur in a good many circumstances and may not signify the presence of diabetes mellitus. For example as stated elsewhere transient hyperglycemia and glycosuria occur frequently in hyperthyroidism. Hyperglycemia and glycosuria also occur after the injection of epinephrine and on the same basis during acute emotional strain or in the presence of certain tumors of the adrenal medulla. A few nondiabetic persons have a brief rise in blood sugar above their renal thresholds and excrete traces of glucose after the ingestion of large amounts of sugar—this is known as *alimentary glycosuria*. Hyperglycemia and glycosuria occur not infrequently in severe meningitis and in certain injuries to the brain. The history and other findings serve to differentiate these disorders from diabetes mellitus.

An unusual condition in which considerable quantities of glucose appear in the urine is "*renal glycosuria*." In at least certain cases this results from an inborn error of metabolism in which the normal reabsorption of glucose fails to take place in the renal tubules (Fanconi's syndrome). Patients with this disorder resemble animals poisoned with phlorizin in that they do not have hyperglycemia and the degree of glycosuria is essentially independent of

FIG. 70. Effect of diet upon the glucose tolerance curves (after Conn). 1 Test done on admission in severe undernutrition. 2 After two weeks 3000 cal 300 gm CHO 80 gm P. 3 After seven days 1600 cal 20 gm CHO 50 gm P. 4 After seven days 3000 cal 300 gm CHO 80 gm P.

the carbohydrate intake. Young people with alimentary glycosuria or renal glycosuria should be considered potential diabetics and should be reexamined at frequent intervals particularly when a family history of diabetes has been elicited.

Lactosuria is not uncommon in pregnancy but is not related to diabetes mellitus. Levulosuria, galactosuria, pentosuria, and maltosuria are rare conditions not as a rule associated with elevation of the blood sugar. The nature of the sugar excreted should be determined in all cases of atypical glycosuria.

**Treatment.** During the past decades the treatment of diabetes has become greatly simplified and it should now be the responsibility of the family physician rather than the specialist to treat the numerous patients who seek his aid. Nevertheless it can not be overemphasized that the successful treatment of diabetes continues to demand the closest attention to detail by both the physician and the patient.

The aim of therapy in diabetes mellitus should be directed towards maintaining health, happiness and normal nutrition on a regimen which keeps the patient approximately sugar free.\* This can be achieved

The aim of maintaining the patient approximately sugar free has been challenged by Tolstoi who administers insulin and disregards the degree of glycosuria provided that ketonuria and the loss of nitrogen do not develop. It remains for the future to determine whether or not this seeming laxity in management will add materially to the incidence of arterial disease, neuropathies and retinitis.

easily in the vast majority of patients with but little modification of the patient's way of life. In a few patients the so-called brittle diabetes satisfactory regulation is extraordinarily difficult even for the specialist to achieve and in these patients intermittent glycosuria is preferable to a life dedicated to the testing of urine.

The management of diabetes must be based upon two principles. The first is the establishment of a dietary regimen with or without insulin in accordance with the aims set forth for therapy. The second is the education of the patient so that he understands (1) the nature of the fundamental disorders in his disease, (2) the preparation and regulation of his diet, (3) the method of testing his urine for sugar and ketone bodies, (4) the technique of self-administration of insulin when this is required, and (5) the complications which may occur and how they should be met. The diabetic patient should be taught to assume the role of the physician and the latter should assume the role of the consultant in routine management of this disease. These principles are put into practice most simply and effectively and with the least loss of time if the patient with severe disease is hospitalized for regulation and training at the time the diagnosis is established. At the outset the importance of the patient's reactions to his life situations cannot be overemphasized in terms of the success or failure of therapy.

One of the first and most important questions which arise in the regulation of a diabetic is whether insulin will be required or whether dietary restriction alone will suffice to achieve the aims of therapy. Upon the decision reached will depend the amount and distribution of the carbohydrate in the diet, frequency of collection of urine specimens, the times of meals, the economic factor involved in the provision of insulin and to a large extent the education of the patient. Whether or not insulin will be required cannot be answered dogmatically and the method of trial and error must frequently be invoked. This is particularly true in patients whose disease process for one reason or another may at one time be severe and at another time mild. For example, in the presence of infection or hyperthyroidism insulin therapy may be essential and yet after subsidence of activity dietary regulation alone may suffice. In spite of these apparent difficulties in arriving at an important decision the following generalizations can be made

and serve as useful guides: (1) the majority of older obese patients in whom the disease is essentially without symptoms do not require insulin, and (2) all diabetic children, young adults and most older patients who acquire the disease acutely with the characteristic symptoms of polydipsia, polyuria, rapid loss of weight and strength require insulin therapy. The percentage of patients with diabetes who can be regulated without insulin varies in different clinics according to the type of regimen established, the standards for adequate treatment, the intelligence of the patients as a group and many other factors. According to Adlersberg and Dolger, 46 per cent of their series of 1131 patients more than fourteen years of age did not require insulin and were treated with diet alone. These patients were undoubtedly in the older age group and were presumably overweight.

**Dietary Treatment without Insulin.** This form of treatment as mentioned before is applicable only to the management of the relatively mild diabetes encountered in obese patients, most of whom are more than fifty years of age. As stated under Etiology, the control of obesity in these patients usually suffices to render the urine sugar free and to reestablish an essentially normal blood sugar level. It is rarely necessary nor is it advisable to attempt to reduce body weight all the way to the ideal value in these patients. Further, more reduction in weight should be gradual since rapid reduction with extreme curtailment of carbohydrate may initiate ketosis and intensify the diabetic process. If regulation is not accomplished without the establishment of undernutrition or if loss of weight is accompanied by significant loss of strength or marked ketosis, insulin therapy is indicated.

The most important rigid dietary restriction to be initiated is the omission of free sugar from the diet. This includes candy, cake, ice cream made with sugar, pastry, fruits preserved with sugar, jam and so on. When sweetening is desired, saccharin should be used in the preparation of foods. The diet should be limited as to its content of foods containing high concentrations of starch, e.g., bread, potato, macaroni, spaghetti, rice, cornstarch or tapioca. The patient should not be allowed more than three slices of bread daily and more than one small serving of any of these other foods mentioned. The reason for these limitations is the fact that the availability of glucose in foods having high concentrations

of carbohydrates results in rates of absorption which may exceed the rate of utilization by the diabetic and therefore may give rise to hyperglycemia and glycosuria. The remaining carbohydrate of the diet should be in the form of vegetables and fruit with relatively low concentrations of carbohydrate  $\approx$  12 per cent or less. It is desirable to have the daily carbohydrate ration divided approximately equally in the three meals.

Protein should be permitted as desired but for most patients 1 to 1.5 mg per kg of "ideal" weight is sufficient. Fats may be allowed in any form but the total daily food intake should not exceed 1200 to 1500 calories. Care must be taken in the selection of foods in this limited regimen to provide for vitamin requirements.

When the desired reduction in body weight has taken place and the urine remains sugar free the caloric intake may be gradually increased to prevent further weight loss. If this increase in diet results in the reappearance of glycosuria or of a fasting or two-hour postprandial blood sugar level in excess of perhaps 150 mg per 100 ml treatment with insulin becomes indicated.

Patients following this simple type of regimen should during the period of desugarization collect twenty-four hour specimens of urine to be tested for sugar and ketone bodies. After the urine becomes sugar free the patient should test an early morning specimen for glucose—this should then become a lifetime habit.

There is no need for frequent determinations of the blood sugar level in these patients. When the urine becomes sugar free it is well to determine the fasting level in order to establish whether or not an unusually high threshold is present. Thereafter it may be of interest to determine the fasting blood sugar level at intervals of about six months unless complications intervene.

**Treatment with Insulin** When the decision to use insulin has been reached time is saved if the patient is at once started on the diet which it is anticipated will meet his energy requirements and as far as possible his desires. The amount of carbohydrate which the diet should contain has long been a matter of controversy. In the opinion of the writer the satisfaction of the patient and his nutritional state are the important determining factors. Most patients are satisfied with diets containing 150 to 250 gm of carbohydrate. Insulin-treated patients as well as those being

treated with diet alone should not be permitted the use of free sugar.

The distribution of carbohydrate among the three repasts is a matter of detail which however assumes great importance in successful regulation. The optimal distribution depends upon individual responses and still more upon the type of insulin used. There is therefore no hard and fast rule to be followed in the partition of the daily carbohydrate ration but when the slow acting protamine zinc insulin (PZI) is used the majority of patients are best controlled when the carbohydrate ration is divided into  $\frac{1}{3}$ ,  $\frac{1}{3}$ , and  $\frac{1}{3}$  among breakfast, lunch and dinner or when part of the evening ration (e.g. a slice or two of bread and butter) is saved for a bedtime feeding. When globin NPH or lente (IZS) insulin is employed more frequently part of the noon ration is needed in mid afternoon to avoid shock. If the carbohydrate of a patient receiving protamine zinc insulin is divided into thirds it may be expected that the patient will experience hypoglycemia in the early morning hours and heavy glycosuria after breakfast. This phenomenon may be termed *paradoxical glycosuria* since the hyperglycemia and glycosuria probably result from epinephrine release following intense hypoglycemia during sleep. It can be established by determining the blood sugar level at about 3 A.M. and should be treated by reducing the dosage of long acting insulin. If a patient has been established on a regimen with regular insulin given twice daily (a regimen rarely indicated today) distribution of the carbohydrate ration into  $\frac{1}{3}$  and  $\frac{2}{3}$  usually proves the most satisfactory. When a mixture of regular insulin and protamine zinc insulin or NPH insulin is used or when globin insulin or lente insulin is given many patients are best controlled with carbohydrate divided equally among the three meals. However individual variations are great and many patients require a part of the noon ration of carbohydrate in mid afternoon and others require part of the dinner ration at bedtime for satisfactory control as with PZI. The important point to be borne in mind is that the distribution of the carbohydrate among the three meals without any change in insulin dosage often determines the success or failure of therapy.

The amount of protein in the diet should be determined by the amount necessary for normal nutrition and by the patient's desires. In most cases amounts between 60 and 100 gm daily prove adequate to meet these demands.

When the carbohydrate and protein rations have been decided upon enough fat should be included to provide the calories necessary to fulfill energy requirements. If patients exhibit a distaste or intolerance for fat or if their desires for carbohydrate are not satisfied the latter foodstuff should be increased and the fat correspondingly decreased. Rigid control of the fat intake is of considerably less importance for satisfactory regulation as might be expected than is control of the total carbohydrate intake and its distribution in the meals. How much the rigid restriction of fat and cholesterol will decrease the diathesis for atherosclerosis in diabetics remains to be established.

During the period of regulation in the hospital it is most helpful to have the patient deviate as little as possible from his anticipated way of living both with regard to physical activity and time of meals otherwise many unnecessary adjustments of diet and insulin become essential when the patient returns to his home and normal existence.

In the education of the diabetic regulated with insulin it is essential that he be instructed promptly in the preparation of a standard diet from which in the future he will be able to make indicated adjustments and add to the variety of his meals with the aid of tables of food values. (The *Diabetes Guide Book* of the American Diabetic Association will be found most helpful to physicians and patients in the preparation of menus.)

During the regulation of patients treated with insulin the urine should be collected in four parts during each twenty-four hours: the first sample from before breakfast up to lunch time, the second from before lunch to before dinner, the third from before dinner to bedtime, and the fourth from bedtime to the next morning. Adjustments in insulin dosage, the type of insulin used, and distribution of carbohydrate depend to a large extent upon knowledge of the time of day at which heavy glycosuria tends to persist. Quantitative determinations of the sugar in the urine are not deemed essential for regulation of the patient.

The type of insulin to be used in treatment is to a great extent a matter of choice, but the majority of patients can be treated successfully and with the least inconvenience with a single dose of NPH, globin or lente insulin. About 75 per cent require 40 units or less, about 10 per cent require 65 to 80 units. With the advent of long acting insulin preparations and particularly

with mixtures such as NPH, the former bugbear of two or three injections daily for routine management has been obviated in almost all cases. In patients requiring 40 units of insulin or less a single injection of NPH is usually equivalent to the same dose of PZI and the fluctuations of blood sugar are less wide. Also, night hypoglycemic reactions are less frequent. These comments apply to the use of globin and lente insulin preparations also. Today in many clinics, insulin zinc suspensions (IZS) are considered the insulin of choice for satisfactory regulation and to avoid sensitization reactions.

In apparently mild cases treatment may be initiated with a dose of 10 to 20 units of long acting insulin given subcutaneously one half hour before breakfast. If the diabetes appears severe it may be necessary to start with 40 units. When heavy glycosuria is present time may be saved if supplementary doses of regular insulin are used in the first few days of regulation. For convenience each voiding should be tested for sugar with Benedict's reagent. If a red or orange precipitate forms 10 units may be given and if a yellow or green color appears 5 units should be administered. Further decisions concerning the type of insulin, its dosage, and the distribution of carbohydrate depend on the response of the individual patient. During regulation changes in insulin dosage should when possible be made not more frequently than every other day, since time is obviously required for physiological adjustment to each change. Except in the presence of heavy glycosuria, acidosis, or recurrent hypoglycemia, changes in daily dosage in excess of 5 to 10 units should be avoided.

The intensity and persistence of glycosuria in patients with essentially normal renal thresholds are more important criteria for therapy than are blood sugar levels which may show wide diurnal fluctuations and may at any moment bear little relation to the overall control of the disease. In elderly diabetics with unusually high thresholds, blood glucose determinations are obviously of importance. In these arteriosclerotic patients some degree of hyperglycemia is preferable to hypoglycemia, which often precipitates coronary insufficiency.

In rare instances patients acquire extraordinary resistance to insulin and may be given in excess of 2000 units in a day without significant effect on the blood sugar level or on glycosuria. Lowell found

that one patient acquired a neutralizing antibody for insulin which disappeared after the withdrawal of insulin and reappeared some time after insulin treatment was reinstituted. Local or generalized urticarial reactions constitute the most common allergic response to insulin. This reaction may vanish spontaneously or it may be controlled by antihistaminic drugs or by the use of lente insulin preparations not containing protamine. The combined use of 11-oxy steroids and crystalline insulin may be of value in the management of extreme insulin resistance.

*Hypoglycemic reactions* are likely to occur from time to time in any patient treated with insulin. In most instances reactions are mild, transient and easily controlled. Occasionally, particularly in patients receiving large doses of long acting insulin, protracted or fatal reactions occur and are associated with punctate hemorrhages and other changes characteristic of cerebral anoxia. With intense and prolonged hypoglycemia there may be an increase in the number of cells in the spinal fluid and changes in the electroencephalogram may persist for days or weeks.

The symptoms of hypoglycemia commonly known as "insulin shock" do not make their appearance at any definite level of blood sugar but the diagnosis should be considered doubtful if the blood sugar is over 60 mg (Folin Wu method) or perhaps 45 mg (Somogyi-Nelson method) per 100 ml. In some patients the symptoms of insulin shock do not appear until the blood sugar falls to 40 mg per 100 ml or even lower. The symptomatology is extremely variable but each person tends to follow a reproducible pattern. The commonest complaints in mild shock are a "trembling feeling inside," an empty feeling in the epigastrium, profuse sweating, pallor, rapid pulse and weakness which develop in the course of fifteen to thirty minutes. These symptoms reflect the release of epinephrine and usually follow an abrupt fall in blood glucose. In some cases unfortunately there may be none of these prodromal symptoms; the attack may begin abruptly with disorientation, confusion, delusions, aphasia, ataxia, even loss of consciousness or generalized convulsions. A positive Babinski reaction and other focal neurological signs may be present. In patients using long acting insulin the onset with symptoms of headache, nausea and vomiting are common and tend to be insidious in their appearance and progression. It is important to bear in

mind that shock following long acting insulin not infrequently appears as long as twenty-four to forty-eight hours after the last dose—particularly when large doses are given.

The administration of sugar constitutes the treatment of insulin shock. Every insulin treated patient should carry a lump of sugar to be taken if suggestive symptoms arise. This treatment or better a small glass of orange juice usually suffices to relieve mild symptoms in a few minutes. If the patient cannot be prevailed upon to swallow 20 to 40 ml of 50 per cent glucose may be given intravenously. When severe shock appears in patients taking large doses of insulin shock is apt to recur and is often resistant to treatment particularly if convulsions or loss of consciousness has persisted for some time. In these cases a 1000 ml clysis of 5 per cent glucose may be needed to prevent the reappearance of hypoglycemia. As an emergency measure 0.5 to 1 ml of epinephrine may be given subcutaneously to raise the blood sugar temporarily.

Every diabetic treated with insulin should at all times be provided with an identification card stating that he has diabetes and takes insulin. This is absolutely essential for patients have been killed when on admission to a hospital in hypoglycemic coma the presence of sugar in the urine has led to the administration of more insulin before the blood sugar has been determined. There should be no confusion between the recognition of hypoglycemic coma and coma due to acidosis but a safe rule to be followed is to administer glucose when in doubt after a sample of blood has been taken for determination of sugar and carbon dioxide.

*Oral Chemotherapy.* A variety of chemical compounds have the capacity to lower the blood sugar of normal man and animals and that of some diabetics. These agents include derivatives of sulfonylureas, sulfonamides, biguanides and other compounds.

Most of these agents lower the blood sugar by injuring the capacity of the liver to elaborate or release glucose into the blood and have been discarded as highly toxic. One compound, 1-butyl-3-p-tolylsulfonylurea, tolbutamide, is receiving wide spread clinical trial. Surely many more chemical agents will be tried because of the laudable aim of finding an orally administered effective nontoxic substance to replace insulin therapy. The mechanism of action of tolbutamide has not been clarified.

fied but evidence that it increases the utilization of glucose at the periphery is not compelling. Yet its effect seems to be related to insulin activity as in most species it does not depress the blood sugar in the absence of the pancreas and it is essentially ineffective in juvenile (insulin deficient) diabetics. It probably also inhibits hepatic glycogenolysis in high dosage.

Tolbutamide lowers the blood sugar in about 65 per cent of all diabetics and about 80 per cent of older diabetics show a response. It is contraindicated in juvenile diabetics and brittle older diabetics. It also has no place in the management of diabetic acidosis. It is most effective in mild obese elderly patients (insulin resistant) and probably a number of those treated have in reality had no need of insulin therapy. *The drug does not reduce the need for meticulous control of diet.* Patients are usually given initially 3.0 gm daily for two to eight days before breakfast and insulin dosage is slowly reduced. Tolbutamide dosage is gradually decreased to maintenance levels of 1 to 2 gm daily.

It must again be emphasized that tolbutamide does not appear to increase glucose utilization and is potentially dangerous. About 3 per cent of patients exhibit side effects including urticaria and other skin rashes, fever and some depression of bone marrow. Alarming diabetic acidosis may develop in severe diabetics when tolbutamide treatment replaces insulin.

**Treatment of Acidosis.** When severe diabetic acidosis develops, immediate and intensive treatment is indicated since recovery is the more likely the shorter the duration of symptoms. The best treatment requires the coordinated effort of medical nursing and laboratory groups in a hospital.

The treatment of diabetic acidosis must be directed primarily toward (1) the restoration of salt and water to the depleted circulating blood volume and interstitial spaces in order to arrest the progression of dehydration, circulatory collapse and renal failure which lead to death and (2) the correction of glycosuria, ketosis and acidosis which for reasons discussed elsewhere give rise to the loss of inorganic base and water.

Upon admission the precipitating cause for the development of acidosis should if possible be promptly determined from the history and physical examination. If an obvious infection, e.g., pneumonia, is present its treatment may be initiated simultaneously with that of the acidosis. At the time of admission blood should be ob-

tained for the immediate determination of carbon dioxide or pH, sugar and urea and for grouping. Through the same needle left in place an infusion of 1500 ml of physiological sodium chloride solution should be started and completed in one hour except in the presence of overt cardiac insufficiency when it should be given more slowly and preferably with measurements of venous pressure. The patient should be given an initial dose of 100 units of regular or crystalline insulin subcutaneously. If the blood pressure is below 90 mm of mercury half of this dose should be given intravenously. If the blood glucose is in excess of about 700 mg per 100 ml an additional 100 units should be given at once. *Long acting insulin should not be used in treating severe acidosis.* If gastric dilatation is present or acidosis is accompanied by recurrent vomiting gastric lavage should be carried out with caution. Fluids orally should be withheld until nausea has disappeared. If the carbon dioxide is reported as less than 20 volumes per 100 ml (9 millimols per liter) a single dose of 20 gm of sodium bicarbonate in 1000 ml of water may be given intravenously. Despite objection by some, this limited use of bicarbonate has distinct advantages. First it replaces directly and promptly one salt lost from the body, i.e., sodium bicarbonate; second it shortens the period of severe acidosis which is particularly deleterious to all patients in shock; and third the utilization of carbohydrate is decreased by acidosis. If the blood pressure does not rise or if severe peripheral circulatory collapse and oliguria are present the initial infusion should be followed at once by the administration of 500 ml of whole blood or an intravenous drip of norepinephrine.

After the initiation of therapy as outlined insulin should be given hourly until ketosis has disappeared. In most cases 50 units an hour prove adequate. Stetten reports the presence of an insulin inhibitor in the alpha 2 plasma globulins in patients with insulin resistant ketosis. Urine specimens should be obtained hourly by catheterization if necessary for sugar and ketone tests. Blood sugar and carbon dioxide determinations should be made at least every 3 hours and if possible also a serum potassium determination. It is advantageous to give enough glucose intravenously to maintain the blood sugar at about 300 mg per 100 ml as long as ketosis persists in order to increase the utilization of glucose and to avoid the possibility of superimposing hypoglycemic shock upon coma due to

ketosis and acidosis. Frequently an infusion of 1000 ml of 5 per cent glucose in water given about three hours after the initial infusion is necessary to make adequate amounts of glucose available and to rehydrate the patient. This solution also decreases the possibility of developing metabolic acidosis due to excessive concentration of the chloride ion and further dehydration resulting from osmotic diuresis due to the excessive sodium ion given. Solutions of fructose have no practical advantage over those of glucose. A number of workers suggest the use of complex hypotonic solutions of sodium chloride lactate and phosphate which may also include magnesium and potassium salts as well as some glucose. Whereas there may in some instances be theoretical reasons for their use the mortality rates are not appreciably lowered by their employment. Probably all patients with severe diabetic acidosis have a fluid deficit in excess of 5 liters which should be replaced parenterally or orally in twenty four hours.

Occasionally significant *hypopotassemia* develops in the course of treatment of diabetic acidosis and results from continued loss of potassium in the urine and a shift of this ion to cells. Decrease in serum potassium may be accompanied by profound muscle weakness involving the extremities and at times the diaphragm resulting in dyspnea. Restlessness, sweating and electrocardiographic changes may also be present. In rare instances patients die from cardiac arrest. This syndrome which rarely appears until after three or more hours of treatment with glucose and insulin is alleviated or can be avoided by the administration of 2 gm of potassium chloride given three or four times at hourly intervals by mouth. If oral medication is not feasible 200 ml of 1 per cent solution of potassium chloride may be given slowly intravenously. Preferable is an infusion of 1 liter of a solution containing 100 milliequivalents of sodium chloride and 40 milliequivalents of potassium chloride. Potassium salts should not be administered in the presence of oliguria or earlier than three hours after the initiation of treatment of the acidosis because of possible potassium poisoning. The fact that Joslin has successfully treated 90 consecutive patients suffering from severe acidosis without potassium salts indicates that the importance of hypokalemia is not great numerically. When nausea has disappeared and ketosis is greatly lessened the patient may be given fluids by mouth on schedule. Water, broth, gruel, diluted milk or orange

juice may be given in small amounts at a rate not exceeding 200 ml an hour. Insulin at this time should be given in accordance with the degree of glycosuria; the urine being tested every two hours. If a red or orange precipitate appears 20 units should be given and if yellow or green 5 to 10 units should be administered. A soft diet with a minimum of fat should be given for twenty four to forty-eight hours after ketonuria disappears and insulin should be administered in relation to the degree of glycosuria as just stated. The patient may then be regulated on his usual diet.

The outline of therapy of *severe acidosis* proves satisfactory in the majority of patients but many factors modify responses; consequently deviations from this regimen must often be made. For example *wide variations in the amount of insulin required are encountered in different patients*. In the presence of persistent infection or hyperthyroidism several hundred units of insulin may be necessary and the tendency for ketosis to recur is great. On the other hand the writer had a patient thirteen years of age who was admitted to the hospital in coma with a carbon dioxide of 15 vol umes per 100 ml who became completely free of ketone bodies and sugar free with a total of only 85 units. In the majority of cases 300 to 400 units are employed. In older persons cardiac failure and pulmonary edema are apt to develop with the liberal administration of fluid given intravenously. In these patients frequent examination of the chest for the appearance of basal rales and measurements of venous pressure serve as a useful guide. Digitalization may prove helpful in this group. If urinary suppression develops it should be treated as indicated elsewhere in this volume.

In the presence of *mild or moderate acidosis* as defined elsewhere the patient should be put to bed; the fluid intake should be increased to about 3 liters a day and sodium chloride to about 10 gm a day should be taken in the form of broth and enteric-coated tablets. Carbohydrate in the form of fruit juices, toast, cereal, potato, rice and milk should be given up to 200 gm a day and fat should be reduced as much as possible in the diet. The urine should be examined every two hours and regular insulin given at the rate of 20 units for a red or orange reaction and 10 for a yellow or green reaction. The basis for acidosis must obviously be sought and corrected if possible.

*Treatment of Surgical Complications*

Surgical procedures no longer constitute a great hazard to the patient with diabetes provided that rigid supervision is exercised. It must be borne in mind however that surgical procedures and anesthesia are potentially capable of inducing ketosis. Immediately before operation an infusion of 1500 ml of 5 per cent glucose in saline should be given and the patient should receive 25 units of regular insulin subcutaneously. Another infusion and the same dose of insulin should be repeated after operation. The urine should be tested for sugar and ketones at two hour intervals. Regular insulin and not long acting insulin should be given as outlined in the treatment of mild acidosis. Unless there are specific contraindications a light soft diet may be instituted on the second day and when the surgical condition permits the patient should again be regulated on his normal diet. If an acute surgical condition e.g. appendicitis has been responsible for the development of severe acidosis operation should be postponed and antibiotics administered until after peripheral circulatory collapse has been treated.

The treatment of infections of the feet has benefited greatly from the introduction of sulfonamide and penicillin therapy. Even in the presence of a seriously compromised circulation there has been a striking decrease in the necessity for amputation.

**Retinitis, Neuropathies and Arteriosclerosis.** The most important measure in the management of these complications is that of possible prevention by adequate dietary control of the disease. Total ablation of the pituitary or the adrenal glands has been recommended to prevent the progression of diabetic retinopathy. At present these procedures do not appear justifiable.

**Pregnancy in Diabetes.** The recognition and rigid control of diabetes in pregnancy is of paramount importance for maternal well being and the normal development of the fetus. All pregnant women should have a two hour postprandial blood sugar determination in the third trimester. Latent diabetes must be rigorously controlled. The value of progesterone and estrogens in the pregnant diabetic is doubtful.

**Hygiene of the Diabetic.** A great decrease in the death rate from diabetes can be brought about by early diagnosis of the disease by frequent routine health examinations and by prevention of complications through education of the patient and cooperation of the physician.

The patient should not be made unnecessarily introspective in the process of his

education but he should never forget that he is a diabetic for laxness in attention to diet or to urine examination sooner or later results in serious consequences. Exercise in moderation is to be advocated for it actually increases carbohydrate utilization to a certain extent. Overfatigue both physical or mental worry unhappiness and lack of "peace of mind" decrease carbohydrate tolerance. Any simple cold or other infection when it develops requires bed care, the liberal ingestion of fluid and the immediate attention of the physician. A patient should never for any reason lower his insulin dosage without first consulting his physician. Likewise digestive "upsets" require the advice of a physician. Many cases of gangrene can be prevented in arteriosclerotic diabetics if they will care for their feet as well as they do their hands.

**Prevention.** Probably the most important factor in the prevention of diabetes mellitus is the prevention of obesity in the community in general. In people with a family history of diabetes the avoidance of excessive weight is mandatory. Experience dictates that "casual" or "alimentary" and "emotional" glycosuria are often forerunners of overt diabetes and should be considered as such. Patients exhibiting these abnormalities should have two hour postprandial blood sugar determinations and should restrict the use of free sugar.

## Spontaneous Hypoglycemia

**Definition.** This term denotes a depression of the blood sugar to abnormally low levels usually in association with a characteristic group of symptoms which occurs without the administration of exogenous insulin.

**Etiology** Seale Harris first recognized spontaneous hypoglycemia by symptoms resembling those which resulted from an excessive dose of insulin. In 1924 he wrote "When I saw the insulin reaction in diabetic patients I realized I had seen many patients (not taking insulin) who had complained of the same symptoms *ie* hunger weakness and the anxiety neuroses." On the basis of symptomatology correlated with blood sugar determination Harris established the presence of spontaneous hypoglycemia in a number of patients. The following classification (modified after Conn) indicates the wide variety of disorders in which spontaneous hypoglycemia may be encountered

**I Hypoglycemia associated with anatomical lesions—"organic"**

**A Hyperinsulinism**

- 1 Pancreatic islet-cell adenoma
- 2 Pancreatic islet-cell carcinoma
- 3 Diffuse hypertrophy or hyperplasia of pancreatic islet tissue

**B Hepatic disease**

- 1 Toxic hepatitis
- 2 "Fatty liver"
- 3 Diffuse carcinomatosis
- 4 von Gierke's disease (glycogen disease)
- 5 Diffuse intrahepatic cholangitis

**C Hypopituitarism (anterior lobe deficiency)—Simmonds disease**

- 1 Destructive lesions *eg* chromophobe adenoma and Rathke's pouch cyst
- 2 Atrophy or infection

**D Adrenal cortical insufficiency—Addison's disease**

- 1 Destructive granuloma—usually tuberculous
- 2 Primary atrophy
- 3 Destructive neoplasms
- 4 Amyloid disease

**E Hypothyroidism**

**F Lesions of the central nervous system *eg* thalamic**

**G Sarcomas and other tumors—mechanism unknown**

**H Alimentary functional hyperinsulinism—following gastric resection**

**II Hypoglycemia without demonstrable anatomical lesions—"functional"**

- 1 Increased secretion of insulin by normal islet cells—autonomic imbalance?
- 2 Decreased secretion of anterior pituitary or adrenal cortical hormones
- 3 Excessive oxidation of carbohydrate in severe muscular work
- 4 Pregnancy and lactation
- 5 Idiopathic hypoglycemia of infants
- 6 Malabsorption syndrome

**III Factitious hypoglycemia (surreptitious insulin administration)**

The mechanisms producing spontaneous hypoglycemia in patients with pancreatic islet-cell tumors with destruction of the anterior lobe of the pituitary gland or with loss of adrenal cortical or thyroid tissue have a recognizable physiological basis

Since hepatectomy is followed promptly by intense hypoglycemia it might also be expected that patients with diffuse disease of the liver would have spontaneous hypoglycemia regularly. It is of interest however that whereas disorders of the liver contributes significantly to the total number of cases of spontaneous hypoglycemia reported its incidence in cirrhosis infectious hepatitis and ascending cholangitis is surprisingly low. Hypoglycemia occurs in all cases of von Gierke's disease. In a few instances hypoglycemia has been reported associated with lesions in the thalamus.

In the majority of patients with spontaneous hypoglycemia without demonstrable anatomical lesions *ie* in cases of "functional" hypoglycemia there continues to be speculation concerning etiology. It seems possible that an increase in secretion of insulin by the islet cells of the pancreas or a decrease in secretion of "anti insulin" by the pituitary or adrenal glands or the pancreas may be of importance but these changes if they do exist have not been demonstrated. It is conceivable but not established that primary disturbances in liver function alter the utilization of carbohydrate without the striking demonstrable changes which for example occur in von Gierke's disease. Hypoglycemia in pregnancy and lactation is possibly related to functional disturbances in the liver or in the endocrine glands which exert an effect on carbohydrate metabolism. Whatever may be the etiology of "functional" spontaneous hypoglycemia its existence and importance cannot be doubted. The relative frequency of various causes for spontaneous hypoglycemia has been analyzed and according to Conn 80 per cent of all cases result from one of three causes namely "functional" hypoglycemia hyperinsulinism with a demonstrable pancreatic lesion or organic disease of the liver.

**Morbid Anatomy** It is clear from the classification of spontaneous hypoglycemia that a variety of pathological lesions may be encountered. Whipple analyzed neoplasms of the islets of Langerhans present in a group of 149 cases of hyperinsulinism. In this group 106 were benign adenomas 15 were outspoken carcinomas and the remaining 28 were questionably malignant. Islet tumors occur most frequently in the body or tail of the pancreas and are often multiple but many escaping detection on surgical exploration are ultimately found to be on the posterior surface of the head. Multiple adenomas of the beta cells associated with hypoglycemia and with

functioning adenomas of the pituitary and parathyroid glands (*endocrine adenomatosis*) have been reported by Wermer. Few cases of hypertrophy of the islands of Langerhans have been well documented. The anatomical lesions of the liver, the anterior lobe of the pituitary gland, adrenal and thyroid glands responsible for the development of spontaneous hypoglycemia have already been mentioned.

Long continued and intense hypoglycemia regardless of the cause gives rise to hemorrhages, cerebral edema and other lesions in the brain that are characteristic of severe cerebral anoxia.

**Physiology.** The concentration of glucose in the blood is the resultant of physiological and biochemical forces engaged simultaneously in the transfer of glucose to and from the blood stream. The body is normally protected against the development of hypoglycemia by various mechanisms discussed in the material on the physiology of diabetes mellitus. A number of physiological factors are probably responsible for the wide range of clinical manifestations of hypoglycemia. These may include (1) the liberation of epinephrine, (2) a sharp decrease in cerebral O<sub>2</sub> A-V difference and an even greater fall in oxygen consumption by the brain without change in cerebral blood flow, (3) the rate of decline of blood sugar, (4) hypokalemia in certain instances, and (5) variations in threshold for symptoms inherent in different persons.

Alimentary functional hyperinsulinism occurring in patients after gastrectomy may result from excessively rapid absorption of glucose with hyperglycemia which stimulates excessive insulin secretion resulting in hypoglycemia.

In severe liver disease hypoglycemia may ensue from the depletion of glycogen stores. It may also result from the fact that the anti-insulin effects of anterior pituitary extract and adrenal cortical steroids and glucagon on carbohydrate metabolism are probably to a considerable extent dependent upon normal liver function. It is conceivable that there might be an increase in utilization of carbohydrate by the tissues in severe liver disease as a result of a decrease in the degradation of fat which takes place chiefly in the liver. Finally, it is possible that degradation of insulin is diminished in severe liver disease.

In the course of severe physical exertion glucose utilization is increased, perhaps because of increased penetration of glucose into cells and may result in transient hypoglycemia. A decrease in blood sugar occurs

in the diabetic as well as in the normal in exercise and therefore may result from an increase in carbohydrate utilization by tissue cells independent of the elaboration of insulin by the pancreas.

**Clinical Picture.** The pattern of the clinical picture in hypoglycemia is extremely varied but in a given person the same symptoms tend to recur though they vary in severity at different times. The hypoglycemic syndrome is almost always episodic. The attacks usually occur before breakfast or several hours after any repast and are frequently precipitated by physical exertion. The episodes vary greatly in duration and intensity. They may last but a few minutes and terminate either spontaneously or after the ingestion of food. On the other hand they may be severe and last for hours or even days and prove resistant to treatment. Occasionally an attack ends fatally. The blood sugar level at which symptoms appear varies; some patients are devoid of symptoms until levels below 40 mg per 100 ml are reached and others present classic symptoms with blood sugar concentrations of 50 mg per 100 ml. The rate of fall of the blood sugar as well as the actual level reached may be a factor in determining the intensity and pattern of symptoms. The symptoms usually associated with a rapid fall in blood sugar level probably result from sudden release of epinephrine and include sensations of hunger, trembling, pallor, sweating, tachycardia and weakness. Symptoms arising from a more gradual and prolonged fall in blood sugar probably resulting from cerebral anoxia include headache, visual disturbances, disturbances in deep reflexes, apprehension, confusion, delusions of grandeur, focal or generalized seizures and coma. The electroencephalogram often shows focal or widespread dysrhythmia which is usually transient but may persist for days or even weeks with or without focal signs after a prolonged and intense bout of hypoglycemia.

**Diagnosis.** To establish the diagnosis of spontaneous hypoglycemia it is essential to demonstrate a depression of the blood sugar level below 55 mg per 100 ml (Folin-Wu method) or 45 mg per 100 ml (Smoggy-Nelson method). In view of the fact that the periods of hypoglycemia are often transient, various means must at times be used for their detection. Four procedures may be recommended: (1) Of foremost importance is the determination of the blood sugar level before breakfast, although it may be normal in many cases. (2) A blood

sugar determination should be made if possible at the onset of an attack. If the attack is convulsive in nature the blood sugar toward the termination of the episode may be normal or even elevated. (3) The glucose tolerance test has limited value and is of use only in patients in whom the fasting blood sugar is normal or in whom it has been impossible to procure a sample at the beginning of an attack. The test is most valuable in the recognition of patients with functional hyperinsulinism who always exhibit a normal fasting glucose level but who develop hypoglycemia with levels below 55 mg per 100 ml (Folin Wu) in response to a stimulating dose of glucose. Hypoglycemia is maximal between three and five hours after the ingestion of glucose. (4) When hypoglycemia is not demonstrable by these means a twenty four to forty eight hour fast should be instituted and blood sugar determinations should be made at six hour intervals. Patients with insulin secreting tumors usually exhibit progressive hypoglycemia with a continuing fast. The prompt alleviation of symptoms and also modification of the electroencephalographic pattern in the direction of the normal with the administration of glucose affords strong evidence for the diagnosis of spontaneous hypoglycemia.

The chief problem of diagnosis from the standpoint of management of the patient is to differentiate if possible hyperinsulinism due to organic disease of the islands of Langerhans from functional hypoglycemia. Both these disorders often escape recognition for months or even years. As a general rule the attacks in functional hypoglycemia are recognized by the response of the blood sugar to glucose stimulation. Furthermore functional hypoglycemia is apt to occur in association with one of the psychoneuroses.

Using criteria which demonstrate unequivocally the presence of severe hypoglycemia Whipple found islet cell tumors in 27 of 32 patients operated on at the Presbyterian Hospital. It is possible that adenomas may have been present in unoperated patients who presented less convincing evidence of hypoglycemia. At times it is essential to resort to surgical exploration to establish the diagnosis but even this procedure is not wholly satisfactory since small adenomas lying deep in pancreatic tissue easily escape detection. Hypoglycemia resulting from organic disease of the pituitary thyroid or adrenal glands or of the liver usually occurs in association with other manifestations of disease of these

structures and consequently presents little difficulty in diagnosis. In any patient exhibiting unexplained hypoglycemia the possibility of factitious hypoglycemia e.g. self administration of exogenous insulin must be considered.

**Treatment** The therapy of spontaneous hypoglycemia can be separated into (1) the treatment of the acute episode and (2) the treatment of the underlying cause.

The management of the attack depends obviously upon its intensity and its response to therapy. Early and intensive treatment of hypoglycemia is of importance to prevent anoxic damage in the brain. Frequently 10 gm of sugar orange juice glucose as candy or a glass of milk will relieve the symptoms and raise the blood sugar to a normal level. When hypoglycemia is more severe and the patient is unable to swallow 0.5 to 1 mg of epinephrine may be administered subcutaneously as an emergency measure and 10 to 20 gm of glucose should be given intravenously in 25 to 50 per cent solution. The injection of glucagon offers little advantage over epinephrine. In cases of intractable or frequently recurring hypoglycemia 1000 ml of 5 per cent glucose can be given by hypodermoclysis. In these patients it is essential also to give by gavage hourly feedings containing both glucose and milk or a casein autolysate until symptoms have been relieved for some hours. When the patient is able to cooperate oral feedings at two hour intervals should be instituted. Despite all therapeutic efforts hypoglycemic attacks occasionally have a fatal outcome.

The management of the underlying causes is naturally dependent upon the nature of the lesion. If the diagnosis is believed to be hyperinsulinism due to an organic lesion of the islands of Langerhans surgical intervention should not be delayed since the frequent feedings necessary to ward off attacks often lead to the development of obesity which adds greatly to the difficulties in ultimate surgical treatment. Steroids or corticotropin and a high protein diet may be tried to control hypoglycemia of sarcomas and other malignant tumors when resection fails.

In patients with functional hypoglycemia in whom the symptoms tend to recur just before meals it is advisable to prescribe a diet high in protein and to reduce the intake of sugar. This regimen appears to be useful. When functional hypoglycemia is associated with a psychoneurosis it is possible that treatment of the latter will reduce the tendency to hypo-

glycemia *Idiopathic hypoglycemia of infants* first recognized by McQuarrie is hereditary. Patients exhibit hypoglycemia on fasting as do patients with islet tumors. The disease regresses with time and can be controlled best with corticotropin.

Spontaneous hypoglycemia due to disease of the pituitary or adrenal glands is not benefited significantly by preparations of these glands now generally available although *adrenocorticotrophic hormone* administered in early hypopituitarism or cortisone in Addisonian patients with recurrent hypoglycemia may prove useful. Treatment is therefore limited to the direct restoration of the blood sugar as outlined previously. In cases resulting from disease of the liver or biliary tract treatment should be directed toward correcting the underlying disorder.

## Obesity

**Definition** Obesity is that physical state in which the amount of fat stored in the body is excessive. It is a symptom which because of its implications and consequences commands the medical consideration accorded serious disease.

**Incidence** Immoderate accumulation of adipose tissue may occur at any age but is more common in middle life. Minor degrees of corpulence (10 or 15 per cent above optimal weight) are the rule rather than the exception after the age of thirty years. In the United States population of 172 000 000 it is estimated that 15 000 000 are 10 per cent overweight and 5 000 000 are 20 per cent overweight. Of these about 4 000 000 are over forty years old. Women are more frequently affected than men. Extreme obesity or localized distribution of the body fat is uncommon and suggests unusual etiological factors.

**Etiology** A plethora of calories is the only explanation of obesity. The law of the

conservation of energy applies to the human body as surely as to any other machine which produces heat and performs work. When the intake of food whether protein, fat or carbohydrate exceeds in caloric value the expenditure as work and heat the excess will be stored in the body tissues. Because of the relatively limited capacity of the body to store protein and carbohydrate the greatest part of the excess is converted into and stored as fat. Thus too much of any type of food is fattening.

**Pathological Physiology** Numerous careful studies have conclusively demonstrated that changes in body weight can be accurately predicted when all metabolic influences are known and measured. The apparently paradoxical situation in which weight is maintained temporarily in spite of low caloric intake is explained by transient water retention. The immediate cause of obesity is always a positive energy balance but there are many ways in which the balance may be tilted toward the positive side. Obesity is often divided into two types: exogenous and endogenous. This classification is not recommended for all corpulence is exogenous (due to an oversupply of food) and likewise endogenous (the reason that the caloric intake is excessive lies within the patient's body).

Although one or more endogenous factors may be present the intake of more food than is necessary is the cause of the excess fat deposit. Enforced inactivity from a broken leg does not cause weight gain but the persistence of "normal" food habits (now excessive) is chiefly responsible. A psychoneurosis may among other symptoms be manifested by *gluttony with resultant obesity* but a similar psychoneurosis may lead to anorexia and emaciation. The difference is in the food intake.

A positive caloric balance may result from an intake greater than normal or expenditure less than normal or a combination of both these influences. Weight is maintained within normal limits in most persons without conscious attention to diet or exercise until the age of thirty or thirty-five. Aberration from a desirable level of intake or from optimal expenditure of energy may result from either physiological or psychological disturbances or both.

**Physiological Factors** A number of the possible metabolic disturbances have been investigated and many attractive theories have been disproved. Digestion of food is not more complete nor is absorption more efficient in obese persons. *Lipophilia* of the tissues consisting in an ability to take

up fat more readily or to retain it more tenaciously than normal has not been demonstrated to account for the usual type of generalized adiposity. *Local factors* must however be invoked to explain the formation of lipomas, the occurrence of lipodystrophy (the commonest type consisting of a lean upper body and obese hips, thighs and legs) and the characteristic fat distribution of certain endocrine disorders.

A basal metabolic rate lower than normal if coupled with an average normal food intake causes fat storage but *low metabolic rates* account for relatively few cases of obesity. The great majority of obese persons have rates within normal limits. Persons with hypothyroidism may be overweight if the appetite is good but often the desire for food decreases in proportion to the metabolic rate. If the metabolism of food (the *specific dynamic action*) were accomplished with less than the usual expenditure of energy, obesity theoretically might result. Recent studies indicate no abnormality in this respect in those who become obese. The *total metabolism* of obese persons is higher, not lower than normal, so weight gain cannot be explained by conservation of energy in work or heat production.

Certain experimentally produced *destructive lesions of the hypothalamus* lead to the rapid development of obesity in animals. Two mechanisms within the hypothalamus appear to regulate food intake: if certain lateral centers are bilaterally destroyed, aphagia results; when the medial control centers are bilaterally destroyed, the lateral "feeding" areas are freed of their usual regulatory checking action and hyperphagia and obesity result. The exact site of the hunger sensation accompanying hypoglycemia is not yet well understood, but studies suggest that glucose levels and perhaps the supply of other metabolites regulate hunger and appetite through the hypothalamic centers. Persons with so-called pituitary obesity presumably suffer from a hypothalamic disturbance. Experimental pituitary destruction does not cause obesity unless the hypothalamus also is injured. Epidemic encephalitis may be followed by the development of obesity and in such cases hypothalamic lesions have been found which resemble those known to cause experimental adiposity.

Certain *endocrine disorders* may predispose to obesity. Frohlich's syndrome, characterized by hypogonadism and obesity, has been considered the result of *hypopituitarism*, but present evidence indicates that the

glandular disturbance is not the cause of the obesity but is an associated phenomenon. In *adiposogenital dystrophy*, the excessive fat accumulation may result from hypothalamic disturbance but its typical distribution is characteristic of hypogonadism, which may result from pituitary insufficiency. Clinically, destruction of the pituitary does not cause obesity, but pituitary cachexia (Simmonds' disease). In *Cushing's syndrome*, there is a peculiar plethoric obesity confined to the head, neck and trunk. This syndrome originally considered to result from pituitary basophilism is apparently not caused primarily by pituitary disease but by prolonged hypersecretion of the adrenal cortex. Similar obesity occurs in some cases of *hyperadrenocorticism* without evidence of pituitary disorder and may be produced by administration of cortisone or related steroid hormones. Although a low basal metabolic rate cannot explain the usual type of obesity, *hypothyroidism* may be associated with gain in weight, partly due to water retention in the tissues and partly to fat storage. Functional or organic hypoglycemia (*hyperinsulinism*) is frequently associated with abnormal hunger leading to excessive food intake and obesity. Removal or destructive disease of the gonads predisposes to obesity; there is less tendency to muscular exertion and there is a moderate fall in the basal metabolic rate. Many women show such changes and gain weight after the menopause and similar but less evident symptoms often occur in men as sexual activity wanes. The adiposity characteristic of hypogonadism involves chiefly the breasts, abdomen, hips and thighs. From these considerations it is apparent that it is inaccurate to speak of endocrine obesity. The endocrine disorder does not cause the obesity but may favor its development by increasing food intake or decreasing energy expenditure or both. Localization of fat deposits is however specifically influenced by certain abnormalities of the internal secretions.

Despite previous popular concepts, the majority of obese children show no evidence of endocrine deficiency; on the contrary, they exceed the average in height and attain earlier sexual maturation.

*Limitation of energy output* in the form of muscular exercise while eating habits remain unaltered causes weight gain and explains the obesity often developing after enforced inactivity following fractures, rest treatment of tuberculosis, poliomyelitis and other diseases.

Obesity occurs more frequently in certain families than in others. In animals the hereditary influence is clearer than among human beings, but even in the latter evidence points to the inheritance of the tendency to obesity.

**Psychological Factors.** Some persons enjoy food more than others because of habit or training eat more than they require and become fat. The food excess need not be great. 15 gm too much of fat or its equivalent in other foods per day will lead to a gain of a pound a month or 12 pounds a year. Family custom or imitation of elders often starts the habit. During periods of athletic activity or strenuous muscular work habits of eating are often acquired which persist for years after the requirement for the high caloric intake ceases. (Normal rats can be trained to eat a whole day's food in one hour; such rats like those with hypothalamic damage convert carbohydrate to fat at excessively rapid rates.) The habit of overeating frequently is established after illness when a concentrated highly nutritious diet is encouraged. Preference for the richer, less bulky foods is often part of a behavior pattern dating from early life, sometimes started by the misguided anxious or overindulgent parent. Some enjoy exercise less and prefer sedentary occupations and will become obese even with an apparently normal diet. Such excessive food intake or low energy output if only moderate in degree can hardly be considered pathological for pleasure in eating and avoidance of exertion are universal human traits. The common moderate obesity of middle age probably results from the persistence of the dietary habits of youth coupled with an increasing disinclination to muscular effort which in turn is due at least partly to diminution of gonadal secretion. The degree of overweight is seldom extreme and reduction by formation of new habits is often easily accomplished.

When obesity is extreme psychological influences beyond such relatively normal limits are suggested. The majority of persons maintain approximately normal body weight without conscious regulation of food intake. Intake is by some mechanism balanced with the caloric requirements. Evidently the metabolic processes and nutritional status of the body normally regulate the psychological drives which govern appetite, satiety and physical energy. These psychological sensations may become deranged so that the usually automatic balance of the intake and outflow of energy

is upset. Pleasure in eating may become a dominant personality trait. The sense of repletion after a meal may require an inordinate amount of food. The sensation of physical energy usually expressed in muscular activity may be depressed.

When social business or sexual desires are unsatisfied the enjoyment of food often becomes magnified in importance and serves as a substitute. Addiction to food like alcoholism is often a symptom of psychological maladjustment. Placid daydreaming in which desires are imaginatively fulfilled may take the place of ambitious exertion so that not only is the caloric intake increased but energy expenditure is diminished. In addition the resultant obesity makes the satisfaction of social and sexual desires less likely and physical exercise more difficult, more discouraging and more fatiguing. A vicious circle thus becomes established which favors further increase in the adiposity.

Obesity may not only be the result of defensive mental processes but the obese state itself may appear desirable to the psychologically maladjusted person for use as a defensive or offensive weapon. It may serve as a defense against undesired contacts or activities for example to avoid sexual advances of an unloved husband or to escape work. In a positive direction it may be useful to gain attention and is often used by children to demand solicitous care.

**Combined Physiological and Psychological Factors.** In the great majority of cases of obesity both physiological and psychological influences may be discovered. For example, adiposogenital dystrophy (secondary to hypothalamic disturbance and hypogonadism) leads to weight gain and the psychic reaction to the sexual deficiency favors the substitution of eating for other satisfactions. Psychosomatic relationships are also clearly evident when emotional disturbance causes ingestion of carbohydrate foods and then the carbohydrate habit results in regularly recurring hypoglycemia due to functional hyperinsulinism with consequent hunger, more carbohydrate ingestion and obesity.

**Morbid Anatomy.** A certain amount of fatty tissue is a normal component of the body, furnishing important structural support and acting as a storehouse of energy. In extreme obesity the subcutaneous fat may be 10 cm or more in thickness and excessive fat deposits occur in the retroperitoneal tissues, omentum, mesentery, perirenal tissues, mediastinum and pericardium.

dium Large deposits may occur in the fascial planes between the muscles and fat infiltration may be found in the pancreas and heart The liver may be enlarged each liver cell containing a large fat vacuole

**Symptoms** Obesity causes dyspnea and fatigue increasing in proportion with the degree of overweight In extreme cases the bulk of the body may cause such mechanical limitation as to result in almost complete incapacity Flat feet and arthritis of the knees and lower back are common and often serious Maceration and infection of the skin beneath rolls of fat occurs Corpulence increases the probability of cardiac failure in heart disease and exaggerates the symptoms resulting from an impaired circulation

In patients without primary pulmonary or cardiac disease severe obesity may lead to alveolar hypoventilation arterial hypoxemia and hypercapnia These changes result in cyanosis reduced vital capacity secondary polycythemia somnolence pulmonary hypertension and right heart failure Adequate weight loss is accompanied by complete disappearance of this cardiorespiratory syndrome

**Diagnosis** Adiposity may be obvious from inspection alone but determination of the ideal weight and the degree of obesity is desirable This may be accomplished within approximate limits by reference to tables or more exactly for each person by calculation from skeletal measurements Use of tables giving average weight at various ages and heights is misleading for the optimal weight of an adult remains unchanged but average weights increase in the middle decades The use of the Wood-Baldwin tables for desirable weights of boys and girls is recommended (published by the American Child Health Association) and for men and women the tables published by the Metropolitan Life Insurance Company The latter tables take into account not height and age but height and relative size of skeleton or body frame

More important in diagnosis than detection of obesity and its severity is discovery of the etiological factors The various possible physiological and psychological disorders must be considered and appropriate methods must be used to investigate the patient's history and habits his physical characteristics and response to special tests Psychiatric study often yields the solution and reveals the obesity as a symptom of a basic maladjustment

**Prognosis** The prognosis can be treated from two viewpoints (1) What is the likelihood of achieving an approximately normal weight? (2) What influence has obesity upon health and longevity?

1 Whether the obese person will accomplish satisfactory weight loss depends upon the effectiveness of treatment The success of therapy depends upon discovery of the etiological factors and their removal or control The physician must find out why the positive energy balance developed and must know how to reverse the process The patient must understand and cooperate If both roles are not well performed the outlook is poor if they are well performed establishing normal weight is not difficult

2 Obesity if persistent impairs health and shortens life The hazard of obesity increases with its degree of severity and with the age of the subject Persons 10 pounds overweight have an increase above the average death rate of 8 per cent when 20 pounds overweight of 18 per cent 30 pounds overweight of 28 per cent 50 pounds overweight of 56 per cent Death from cardiovascular renal disease is 62 per cent more frequent in the obese than in persons of normal weight Cirrhosis of the liver appendicitis biliary calculi and liver and gallbladder cancer occur about twice as often in the obese cerebral accidents and puerperal complications about one and one half times as often Twelve per cent more of the obese die from accidents possibly because of subnormal agility Gallbladder disease is especially frequent in those overweight Obesity predisposes to diabetes especially after age forty The death rate from diabetes is about four times as great in the obese The greater the obesity the poorer the prognosis following surgical operations Persistence to infections such as pneumonia is decreased

**Treatment** Prevention or elimination of obesity depends upon instruction by the physician and dietitian but the patient must carry out his own treatment Therefore the patient must be impressed with the seriousness of the condition and provided with specific means to combat it The physician cannot enlist the necessary cooperation of the patient by condemning him for gluttony or laziness every effort should be made to discover the underlying disturbance in each case

Prevention of excessive weight gain is preferable to and easier than treatment Proper eating habits of those predisposed to obesity for any reason and of persons

entering middle age should be established and unless contraindicated moderate regular exercise should be encouraged.

Weight reduction may be accomplished by decreasing the food intake by increasing the energy expenditure or both. Although the immediate cause of obesity is always a caloric intake in excess of the requirements, treatment which consists solely in giving the patient a low caloric diet outline is seldom successful. This is because the reasons for the positive energy balance are frequently multiple and successful therapy requires removal of the causes, often both physiological and psychological.

Treatment may be divided into two phases: (1) elimination of etiological factors and (2) getting rid of the excess fat stores. For example, if hypogonadism is a causative influence, use of gonadotropins or gonadal hormones is helpful or if hypothyroidism is a factor, thyroid therapy is indicated or if a psychological difficulty is expressed in inordinate eating, its removal is necessary before the patient can reduce weight by dieting. Removal of stored fat may be accomplished by forcing its consumption for the production of body heat and energy. To achieve this, the caloric intake must be reduced or the metabolism accelerated or both. Increase in energy expenditure may be induced by exercise when muscular exertion is not contraindicated by such complications as myocardial disease, orthopedic disorders, and so on. Definite amounts of moderate regular exercise such as walking, golf, and swimming should be prescribed since it not only increases caloric output but improves muscle tone and general health. *Desiccated thyroid* will raise the metabolic rate and facilitate weight loss, but it should be given only when there is definite hypothyroidism and then only in amounts sufficient to maintain a normal basal metabolic rate. *Dinitrophenol* will accelerate metabolism but is toxic and should never be used.

Drugs to induce purging may reduce weight temporarily, chiefly through water loss, but the treatment of obesity is necessarily a prolonged process and repeated catharsis is ineffective and harmful.

Diuresis with weight loss often occurs during therapy with low caloric, low salt diets. The use of diuretic drugs is usually not advisable unless indicated by the presence of edema.

*Diet restriction* is always necessary to induce weight loss (except in the mildest cases), no matter what caused the obesity. An allowance of 35 calories per kilogram

of body weight is a maintenance diet for the average moderately active person. Limitation to 15 or 20 calories per kilogram of ideal weight provides a satisfactory reduction diet which will permit the patient to follow his usual occupation and to lose 1 or 2 pounds a week. For an ideal weight of 70 kilograms (154 pounds), this would amount to 1000 to 1400 calories daily. The protein allowance should be liberal (1 to 1.5 gm per kilogram) because of the high satiety value of protein, its high specific dynamic action, and its importance in protecting tissues and building muscles. Carbohydrate should be taken chiefly in the low-carbohydrate bulky fruits and vegetables and should total 0.75 to 1.5 gm per gram of protein. The fat intake should be minimal, restricted primarily to the eggs and meat necessarily included in the liberal protein allowance and amounting to about 0.5 gm per kilogram of ideal weight. A widely applicable diet of this type providing approximately 85 gm of protein, 35 gm of fat, and 105 gm of carbohydrate (1075 calories) follows: 2 glasses of skimmed milk or buttermilk, 3 slices of whole wheat bread, 1 egg, 2 servings of lean meat, 1 potato, 4 servings of 1 to 8 per cent vegetables (raw, cooked, or in salads), 3 servings of raw or unsweetened canned fruit. The daily food allowance should be divided into three or four meals of approximately equal caloric value; omission of meals should be discouraged. Such a diet should be adequate in calcium, iron, and ascorbic acid but if followed for a long time should be supplemented with concentrates of vitamins A and D and the B complex. Moderate restriction of water and sodium chloride is advisable for patients who tend to retain fluid.

Prescription of a diet does not ensure its observance. The patient must be instructed in the principles and details of the diet. The causes of excessive appetite must be eliminated if possible, and psychological drives encouraging low caloric intake must be substituted. Pride in appearance, desire for physical skills, wish to avoid physical disabilities, and to prolong life.

Dietary instructions should be written and must be explicit and detailed.

Most essential is periodic consultation with the physician to maintain morale, provide encouragement, record weight loss and improved body measurements, and to permit repeated instructions concerning diet and other details of treatment. Too often the obese patient is considered medically unimportant and uninteresting; is given in

adequate instructions and these only once and then is cast adrift to fight his long and difficult battle alone. As in other conditions requiring prolonged therapy dietary control and attention to psychiatric aspects frequent advice from a sympathetic physician is vital. In obesity more than in any other common condition rather simple measures can result in great relief of symptoms and prolongation of life.

Formal *psychotherapy* is seldom required if prolonged cooperation with an understanding physician can be established. More deeply seated psychic disorders or habit patterns may require the attention of a trained psychiatrist.

*Drug therapy* in some cases helps to decrease appetite, especially amphetamine sulfate 5 to 10 mg. one half to one hour before meals usually on arising at 11 A.M. and 4 P.M. (not after 4 P.M. since it causes insomnia).

The physical and psychic effects of successful treatment are usually gratifying. Weight reduction often results in correction of menstrual disorders, diminution in hypertension, decrease in circulatory and cardiovascular strain with relief of dyspnea, fatigue and edema, decrease in joint pain in the engorgement of venous varicosities in the discomfort and disability from hernia, improvement in carbohydrate tolerance and increase in physical and mental efficiency and in enjoyment of the normal pleasures of life.

## Atherosclerosis

**Definition.** Atherosclerosis is a disease in which patches of lipid containing material (atheromas) are deposited beneath the intimal surfaces of blood vessels. It is not to be confused with senile or involutionary arteriosclerosis in which loss of calcium lipid and protein appear as inevitable conse-

quences of the aging of arteries. Its development depends upon causes quite separate from those involved in Monckeberg's medial calcification. Pathogenetically as well as anatomically it is distinct from the arteriolar sclerosis which characteristically accompanies prolonged hypertension. The distinction is significant because senile arteriosclerosis and medial calcification are not often demonstrably consequential in the production of symptoms while the complications of arteriolar sclerosis although serious differ from those of atherosclerosis. In older persons however strict separation of the several forms of arterial disease offers difficulty since atheromatous deposits are seen in vessels which have already developed senile alterations which exhibit variable degrees of medial calcification and which may show the characteristic arteriolar sclerosis of concomitant high blood pressure.

**Incidence.** Postmortem examinations indicate that in more than 50 per cent of North Americans who die before the age of fifty atheromatous plaques are demonstrable and that among those who die after the age of seventy five more than 90 per cent are moderately or seriously affected. That the disease does not spare American youth is indicated by studies of soldiers killed in combat in Korea. In 40 per cent of men averaging twenty two years of age atherosclerotic plaques of some degree were found in the coronary arteries. The disease is so widely distributed as to suggest a defect inherent in mankind. Certain it is that conditions otherwise regarded as normal permit extensive formation of atheromatous patches in blood vessels of a large part of the adult population of North America and northern Europe. The susceptibility of man is the more remarkable since other species of mammals have not been shown to develop spontaneous atherosclerosis.

**Etiology and Pathogenesis.** Although in man the tendency to atherosclerosis appears to be almost universal the rapidity and extent of development of the lesions are modified by a variety of factors. Race appears to have an important influence on the degree of susceptibility. Of people living in the United States Jews are especially prone to the serious effects of the disease. Testimony of many observers indicates that in their native habitat Mongoloids, African natives and the Tamils of southern India are less affected than the Caucasians of the United States and northern Europe. Difficulty is encountered in interpreting the evi-

dence concerning some of the supposed racial differences since the influence of other factors such as longevity eating habits and the frequency and thoroughness of postmortem examinations cannot readily be evaluated. For instance, serious complications of atherosclerosis are rare among Japanese living in their own land but are more frequently encountered among their countrymen in Hawaii and southern California. *Familial and hereditary influences* are potent factors in determining the rate at which atherosclerosis develops. Families afflicted with hypercholesterolemia and especially those in which the cholesterol concentration is so high and persistent as to produce xanthomatosis tend to develop extensive lesions and serious or fatal complications in early life. The degree of atherosclerosis increases with age. Lipid deposits are seldom seen in the newborn although they may develop as yellow streaks in the aortas of unweaned infants within a few weeks following birth. Lesions tend to become more extensive with each succeeding decade a circumstance which is in part the result of accretion of repeated deposits but which may be attributable in some degree to changes in physical and chemical factors in the aging population. Sex appears to exert a significant influence on the rate of development. Women before the menopause seldom suffer from complications of the disease. When compared with men of like age they exhibit less atherosclerosis of the coronary arteries and possibly less deposit in the peripheral vessels. In older women this outstanding advantage appears to be lost and in the later decades of life there is little difference between the sexes either in the extent and degree of the deposits or in the incidence of their serious consequences.

Some physical factors favoring the deposit of lipids in arterial walls have been well established. The lesions tend to occur earlier and to be more florid in areas of intimal thickening. They are exaggerated in locations where syphilis or other injury to the circulation within the arterial wall has previously occurred. That the deposit is to some extent dependent upon a minimum blood pressure is indicated by the fact that pulmonary arteries and veins do not become atherosclerotic unless their intraluminal pressure is materially increased by disease. In otherwise normal individuals the deposit is greatest at sites in the arterial system where the blood pressure is highest. Persistent hypertension exaggerates the tendency to atherosclerosis so sig-

nificantly and constantly that in the past high blood pressure has been regarded as a primary cause of the atheromatous changes.

Although physical factors are undoubtedly important in determining the location and extent of lesions the fact remains that atheromas develop widely in arteries that reveal no evidence of preceding structural changes. Differences in blood pressure and the anatomy of arterial walls have failed to explain the variation and susceptibility between man and other mammalian species. Thus attention has been focused on the possibility that something in the chemical composition of the plasma of man makes him more vulnerable than other species. A number of factors have been emphasized. It has been suggested that the rate and extent of deposit might be dependent upon the cholesterol concentration in the plasma that it might be more influenced by the cholesterol phospholipid ratio that it might depend upon the distribution of lipids between the several lipoproteins of plasma that it might depend upon the actual amount of the lipids combined with beta<sub>1</sub> globulins in the form of beta lipoproteins or upon the concentration of specific forms of beta lipoproteins recognizable in the ultracentrifuge. Investigations have shown that in several of these particulars the plasma of man differs from that of non-susceptible mammals and that the divergence is greatest in physiological states and in diseases which appear to predispose to more rapid and more extensively atheromatous deposit. In general observations lend strong support to the chemical hypothesis for the pathogenesis of atherosclerosis although they do not establish any one chemical factor as solely responsible. It now seems not unlikely that atheromatous deposits are dependent upon chemical factors operative to some extent in all human adults but grossly exaggerated with familial predisposition and with a variety of diseases.

Pathogenetic significance has been attributed to other circumstances. There is some statistical evidence that habitus is important and that the disease appears earlier and more extensively in mesomorphic persons. Heavy indulgence in alcohol over many years has seemed to afford some protection while excessive use of tobacco has been urged as a contributing factor to the development or aggravation of complications. A low caloric vegetarian diet has been regarded as protective whereas consumption of animal fat has been thought to exaggerate the deposit. It has been stated

and contradicted that the obese develop a greater degree of atherosclerosis than the spare. Abundant evidence supports the contention that grossly overweight persons suffer at an earlier age the serious consequences of the disease.

**Pathology.** Atherosclerosis is preeminently a disease of the aorta and its branches. It is minimal or absent in pulmonary arteries except in conditions such as mitral stenosis which cause pulmonary artery hypertension. It is not seen in the walls or veins except after injury from phlebitis or at sites of arterial venous aneurysms. It appears early on the posterior wall of the aorta at the openings of the intercostal arteries and also at the mouths of the coronaries. It is more abundant in the descending than in the ascending aorta, more evident in the abdominal than in the thoracic portion. Atherosclerosis is patchy in its distribution and extensive lesions in vessels of one organ may develop with almost complete freedom from involvement in other parts of the vascular system.

The early atheromatous patch consists of cholesterol, cholesterol esters, phospholipids and neutral fat together with a considerable amount of protein. When first deposited its composition mimics that of the blood. The earliest lesion appears as a yellow linear streak slightly raised above the surface. The deposit begins in the deepest part of the intima and the lipid may be seen partly in the intercellular ground substance and partly in the intimal connective tissue cells, some of which are distended with fat to such a degree that they have been called foam cells, lipid cells or lipophages. Gradually the fat extends to the surface of the intima. The connective tissue over the fatty area becomes thickened, necrosis may develop in the deeper part of the plaque, cholesterol crystals become more abundant because of the disintegration of cholesterol esters. The area becomes calcified and in some instances somewhat vascularized. The amorphous fatty tissue accumulates and at times to an extent which may cause rupture of the intima with ulceration and production of a site favorable to the formation of thrombi. In large vessels such as the aorta and its main branches intimal plaques have no appreciable effect on the lumen. In smaller vessels such as the coronaries or the arteries at the base of the brain the plaques may accomplish almost complete occlusion and may lead to ischemia or infarction of tissue. More often however these accidents are dependent upon throm-

bosis or hemorrhage on the thickened or ulcerated surface of a narrowed vessel.

**Clinical Manifestations.** Extensive lesions may exist for long periods without producing clinically recognizable abnormalities. The disease need not be widespread, however, to produce serious symptoms. A single atheromatous plaque strategically placed may lead to a serious or fatal accident.

Clinical manifestations may be limited to fatigue and a diminished capacity to perform mental or physical tasks. Localizing signs may develop in any part of the body but are usually referable to disturbances in circulation of the heart, brain, extremities or gastrointestinal tract.

**Manifestations Referable to Ischemia of the Heart Muscle.** In the United States atherosclerosis of the coronary arteries is the most frequent cause of heart disease. The most distinctive clinical manifestations are angina pectoris and myocardial infarction. Pathological experience indicates that 90 per cent of patients suffering from anginal pain exhibit at autopsy obstructive narrowing or occlusion of the main coronary arteries or their primary branches. Causes of myocardial infarction other than atherosclerosis of the coronary arteries are extremely infrequent. In the absence of angina pectoris or the signs of myocardial infarction the presence of coronary atherosclerosis even when it has produced extensive narrowing and multiple occlusions may be clinically unrecognizable. Although bundle branch block and other disorders of the conduction system, ventricular tachycardia, diminished cardiac reserve and heart failure are common manifestations of the myocardial ischemia of coronary atherosclerosis, they occur also in hypertension and other conditions with sufficient frequency to rob them of diagnostic significance.

**Manifestations Attributable to Atherosclerotic Disease of the Aorta.** Even massive atherosclerosis of the aorta may be clinically unrecognizable except by roentgenographic visualization of intimal calcification. Rarely when combined with hypertension and dilatation of the aortic ring it may contribute to incompetence of the aortic valve. In syphilitic aortitis atheromatous plaques tend to be excessive where the arterial wall and its internal circulation have been damaged by the spirochete. Sacular aneurysms are not attributable to atherosclerosis although their walls may contain many atheromatous plaques. Dissecting aneurysm which was formerly attributed to channeling of the blood beneath

fractured calcified patches of atherosclerosis in the presence of hypertension is now usually ascribed to cystic degeneration of the media. In the abdominal aorta repeated and progressive thrombosis at the site of atheromatous patches may occlude the great vessel sufficiently to produce peripheral ischemia and manifestations of the Leriche syndrome.

**Clinical Manifestations of Cerebral Atherosclerosis** Together hemorrhage and thrombosis of cerebral vessels constitute 90 per cent of all cerebral vascular lesions. In both processes atherosclerosis is significantly implicated for it is recognized as the most frequent cause of cerebral thrombosis and traditionally hemorrhage has been thought to result from the rupture of an atherosclerotic vessel in the presence of hypertension. Furthermore before actual blockage or hemorrhage occurs progressive occlusion of vessels leads to ischemia with patchy degeneration of cortical cells and nerve tracts and disseminated areas of atrophy. Actual obstruction with or without thrombosis leads to small or large areas of softening. Numerous small lesions as well as larger ones may result in paralysis or in mental deterioration which clinically overshadows the loss in motor function. They cause diminution in intellectual capacity, impaired memory especially for recent events and names, emotional instability, addiction to reminiscence with more or less confabulation. The victim becomes self-centered, hostile and sometimes paranoid with loosely constructed delusions. Actual dementia is not uncommon. Progressive intramural clot formation on atheromatous patches in the internal carotid arteries by interfering with cerebral circulation may cause transient paralyses and unilateral blindness or may simulate neurological defects more frequently caused by disease of the cerebral vessels.

**Manifestations of Atherosclerosis of Peripheral Arteries** Atheromatous disease is by far the commonest cause of arterial occlusion in the legs. Except in diabetics symptoms referable to its presence are uncommon before the age of fifty-five. In the arms serious impairment of circulation from atherosclerosis is not frequent and the calcification which is so often demonstrable in the radial, ulnar and brachial arteries of older persons is usually attributable to medial rather than intimal disease. Obliterative lesions in the terminal branches of the posterior tibial and dorsalis pedis arteries produce symptoms which in their early stages consist of paresthesias,

nocturnal cramps, weakness and chilliness of the legs and feet. Later faint discoloration of the ends of the toes may be followed by more serious circulatory disturbance or by dry or moist gangrene. In many patients the most troublesome symptom is intermittent claudication which consists of cramping pain that appears with walking and subsides with rest. This may develop before the signs of complete arterial occlusion are apparent. Prominent physical signs are lack of pulsation in the peripheral arteries, blanching on elevation of the foot with slower than normal return of color with dependency. The veins remain collapsed for some time.

**Manifestations of Atherosclerosis of the Mesentery Vessels** Digestive disturbances including achlorhydria, intestinal atony and constipation which are frequent in the aged have been attributed without convincing proof to the impaired circulation and ischemia of atherosclerosis. Thrombosis of the mesenteric arteries like that of the coronary and cerebral vessels may depend upon the formation of an intraluminal clot at the site of an atherosclerotic patch.

**Diagnosis** As yet there is no adequate clinical or laboratory means of estimating the degree and extent of atherosclerosis or even of recognizing its presence. Lesions may be suspected because of the visibility by roentgenographic examination of calcified lesions in the aorta and its main branches. Tests of tolerance to exercise and response to deprivation of oxygen, balistocardiographic observations and electrocardiographic studies may permit the inference that the coronary circulation is insufficient. Careful measurement of the pulsations in the extremities may indicate defects which are usually ascribable to atherosclerosis. Unfortunately even with the use of all of these tests the existence of atheromatous plaques often is not established until serious complications have already developed.

**Treatment** In considering the treatment several objectives may be kept in mind: (1) It would be desirable to limit or prevent the deposit of lipids or to cause the disappearance of lesions already formed. (2) It would be an advantage to control hypertension which is thought to accelerate the deposit and to favor rupture of atherosclerotic vessels. (3) Most desirable of all would be the prevention of intraluminal clotting which is responsible for a large part of the mortality and morbidity of the disease.

Criteria for judging the degree to which

any one of these desirable objectives is achieved are unreliable. Since we cannot satisfactorily recognize the location and extent of atheromatous lesions we cannot tell whether they are affected by therapy. Under the best circumstances judgment concerning efficacy of management would require statistical analysis of an immense experience.

A vast number of remedies have been suggested and tried. Of the more recent ones a word may be said. Neither the efficacy nor the rationale for administration of choline, methionine, lipocain, and inositol has been established. The use of heparin recently suggested with hope deserves further study. As yet its efficacy in accomplishing any of the objectives of treatment has not been proved. It has been shown that the administration of estrogen can modify the cholesterol concentration and abnormal lipid pattern of survivors of myocardial infarction to a degree which in many cases amounts to reestablishment of normal chemical conditions. It has not been demonstrated that the administration of a female sex hormone inhibits or prevents the development of atherosclerosis or exercises any influence on the incidence or severity of its complications. Side actions of estrogens, chiefly impotence and gynecomastia, are so undesirable as to preclude their extensive therapeutic trial.

In patients who have suffered myocardial infarctions carefully controlled anticoagulant therapy has aided in the prevention of still more serious complications. Success in this situation has suggested the more extensive use of anticoagulants in the prophylaxis of thrombosis in those who appear to be especially threatened by the degree and location of their atherosclerosis.

In recent years chief attention in the treatment of atherosclerosis has been focused upon the use of diets with chief emphasis on restriction of cholesterol, fat, and caloric intake. Extensive trial of diets low in cholesterol alone has failed to show crucial changes in the cholesterol concentration of the plasma or in most of the essentially pathological features of lipid composition in persons especially susceptible to the development of atherosclerosis. There is more convincing evidence that limitation of dietary fat might be beneficial. Studies by Keys on population groups in various parts of the world have shown a close correlation between the percentage of total dietary calories derived from fat, concentration of cholesterol in serum, and

incidence of myocardial infarction. Those people who consume the most fat show the highest concentration of serum cholesterol and the highest incidence of coronary heart disease. Myocardial infarction appears to be rare among people who habitually take less than 20 per cent of their total calories in the form of fat. Observations by Ahrens, Kinsell, and Malmros suggest that the form as well as the total amount of fat may be important in the pathogenesis of atherosclerosis. Substitution of equal caloric amounts of corn oil for dairy fat in a balanced diet is predictably accompanied by a reduction in concentration of serum cholesterol. These recent dietary studies have definite therapeutic implications. Even in their present incomplete state they suggest the advisability of both quantitative and qualitative modification of fat intake for persons especially predisposed to atherosclerosis and its complications. As yet they are not sufficiently conclusive to permit recommendations for radical reform in the national diet. While we wait for more complete data it is possible however to offer some general advice.

It is no new doctrine that gluttons have a relatively high morbidity and mortality from vascular disease or that there is greater average longevity and relative freedom from vascular accidents among the spare and the frugal. More recent evidence has strengthened this traditional impression. It is stated with statistical support that the obese have a greater incidence of hypertension and that atherosclerotic plaques develop earlier and more abundantly in the overfed. Some evidence has been presented that life expectancy may be increased by correcting overweight. This circumstantial evidence seems to indicate that a low fat, low but adequate caloric diet may be advised with the expectation of partial protection against the rapid development of the complications of atherosclerosis. Since man is an atherosclerotic animal and since atheromas form to some degree in most people in middle and later life, this advice need not be limited to those already obese or to those who have disclosed the obvious presence or complications of atherosclerosis.

## Xanthomatosis

**Definition** Xanthomatosis as defined in this section includes only those conditions in which deposits of lipid in tissues are dependent upon or accompanied by abnormally high concentrations of lipids in the blood. Not included are several clinical states which are sometimes given the name of xanthomatosis and are characterized by lipid containing histiocytes or reticular endothelial cells but which develop without perceptible hyperlipidemia (See Niemann Pick's Disease Hand Schuller Christian Disease).

Lipid accumulation may consist chiefly of cholesterol (hypercholesterolemia) or of neutral fat (hyperlipemia) and xanthomata may develop in either condition. Chemically separation of the two states cannot be sharply made since many cases of hypercholesterolemia exhibit moderate increase in the plasma concentrations of neutral fat and most cases of hyperlipemia have higher than normal plasma concentration of cholesterol. Attempt at distinction is useful however because of differences in clinical manifestations.

**Etiology and Pathogenesis** *Hypercholesterolemia* The mean cholesterol concentration for young normal adults is about 200 mg per 100 ml with a rather wide range from 120 to 280 mg per 100 ml. In older normal persons of both sexes the mean as well as the maximum concentrations are moderately increased. Although there are large differences between members of a group the range of concentration in each individual is seldom more than  $\pm 15$  per cent under a considerable variety of life situations. Hypocholesterolemia normocholesterolemia and hypercholesterolemia are relative terms and the dividing line between the normal and the pathological is entirely arbitrary. In this discussion we have set 300 mg per 100 ml as the upper limit of normal but with the suspicion that values below this level may be con-

sequential in the tendency to deposit of lipids in tissues.

Hypercholesterolemia has been observed under a variety of conditions but may be classified rather simply as *familial* or *idiopathic* and *acquired* either in the course of diabetes nephrosis or myxedema or as a consequence of hepatic and biliary tract disease.

By far the commonest cause both of excessive concentration of cholesterol in plasma and of xanthomatosis is *essential familial hypercholesterolemia*. That it is hereditary is attested by many observations of family groups in whom hypercholesterolemia xanthomatosis premature atherosclerosis and coronary heart disease are so frequently encountered as to be considered parts of the same genetic defect. Active discussion in the literature continues on the question of whether inheritance can be explained on the basis of a simple dominant or an incompletely dominant gene.

Hypercholesterolemia from secondary causes is seldom sufficiently severe or prolonged to cause deposit of lipids in the skin. When these do appear they take the form of eruptive xanthoma and usually consist of small papules pinhead to pea size subcutaneously located on the trunk and extremities and surrounded at their inception by hyperemic halos. In the arteries extensive deposit of lipids and the clinical complications of atherosclerosis may accompany both diabetes and nephrosis. In myxedema the pathological evidence of more than usual atherosclerosis is less convincing although relative frequency of angina pectoris in this condition has been noted.

The hypercholesterolemia and xanthomatosis which accompany hepatic and biliary disease is seen most often in cases of long standing biliary cirrhosis. Higher than normal concentrations of plasma cholesterol are also frequently encountered in a variety of obstructive lesions of the biliary tract but seldom lead to xanthomatosis of the skin or tendon sheaths. In these conditions clinical complications of atherosclerosis are rare although superficial deposits of lipids have been noted in the postmortem examination of the aorta and the endocardium.

**Hyperlipemia** Like hypercholesterolemia the excessive accumulation of neutral fat in the blood may be due to primary or secondary causes. It may be simply classified as (1) *essential familial hyperlipemia* and (2) *acquired from nephrosis diabetes von Gierke's disease chronic pancreatitis* or a variety of miscellaneous conditions.

The family disease is regarded as a rarity

Only a few cases have been recorded. Since its presence does not interfere with the maintenance of apparently good health over long periods there is reason to think that it is commoner than a review of the literature might indicate. Acquired hyperlipemia is seen more frequently. It is a part of the nephrotic syndrome where it is always associated with hypercholesterolemia. In a few diabetics hyperlipemia may be extreme and when present is accompanied by greater than normal concentration of all other lipid components. Xanthomatosis accompanying hyperlipemia less often involves the tendon sheaths and may take the form of the eruptive xanthoma that is seen in acquired forms of hypercholesterolemia. The lesions appear to represent a spillover from the hyperlipemic plasma into highly vascularized tissue. Similar forms have been occasionally noted in association with von Gierke's disease and in association with chronic pancreatitis.

**Pathology** The lesions of xanthomatosis tend to be quite similar pathologically regardless of location. There is a deposit of lipid and in the hypercholesterolemic families chiefly of cholesterol in subcutaneous and cutaneous tissues, tendons and aponeuroses. Cholesterol crystals may be evident. Connective tissues containing fat and variously called xanthoma cells, foam cells or lipophages tend to accumulate. In some of the lesions there are giant cells (Touton cells) which contain several nuclei in an almost complete circle around an opaque cytoplasm. The lesions are most easily recognized in the skin and tendons but those which develop in the structure of internal organs such as the heart and arteries do not differ materially from the superficial lesions. In the eruptive xanthomas much of the lipid is extracellular. Foam cells are not numerous, giant cells are absent, little granulation tissue is seen.

Chemically there are significant differences in lipid distribution in plasma of the several forms of xanthomatosis. In both familial hypercholesterolemia and familial hyperlipemia cholesterol/phospholipid ratios exceed unity and lipids are concentrated in lipoproteins formed from normal beta<sub>2</sub> globulins. In xanthomatosis accompanying primary biliary cirrhosis concentration of phospholipid is twice that of cholesterol and both are combined with globulins in the form of abnormal beta lipoproteins.

**Clinical Manifestations** In many cases both of hypercholesterolemia and hyperlipemia clinical recognition must depend solely upon chemical tests. Unsurprisingly,

any obvious symptoms or physical signs. The condition of the patient during life may disclose no evidence of the underlying defect or its anatomical damage.

Xanthomatosis has been noted most often and in its most obtrusive clinical forms in association with familial hypercholesterolemia, although other forms of hypercholesterolemia and hyperlipemia may mimic the clinical picture of the familial disease. The lesions are various and have been given many names.

*Xanthelasma* is a term used to indicate collections of fat and cholesterol in the eyelids. Although these are frequent accompaniments of hypercholesterolemia and are occasionally seen in association with hyperlipemia, it is important to remember that the lesions may be present in patients who exhibit no chemical defects. *Arcus senilis* in relatively young people like xanthelasma is a frequent accompaniment of hypercholesterolemia but may develop in people as in the Eskimos in whom no chemical defect in the plasma can be demonstrated. *Xanthoma planum* is the term reserved for flat or slightly raised lipid deposits seen in many parts of the body but with special frequency in the creases of the palms in the folds of the elbows in the creases below the breasts and in wrinkles or folds elsewhere. *Xanthoma tuberosum* is a name given to nodular lipid deposits in the skin. It appears in many places but may develop floridly on the buttocks, elbows, knees and hands. *Xanthoma tendinosum* is a term used to describe hard nodules of lipid deposits in the tendon sheaths of hands, forearms, ankles and many other sites.

It is to be noted that these different forms and localizations of deposits do not represent separate diseases. On the contrary, all of them may be evident in the same individual. The distinctions are not qualitative but are used entirely for descriptive purposes.

**Vascular Involvement** Those who suffer from familial hypercholesterolemia and xanthomatosis may deposit cholesterol and develop collections of foam cells or lipophages beneath the intima of blood vessels and occasionally beneath the endocardium. These lesions cannot be strictly differentiated from the atheromatous patches which are found in persons who have normal concentrations of cholesterol in the plasma. They are notable chiefly because of their development in younger persons and because of their greater degree and extent. The formation of xanthomas in the vascular system is usually localized to blood

vessels and chiefly to the aorta and its branches with frequent and early involvement of the coronary arteries. The deposits may be seen in pulmonary arteries and in a few cases have implicated the endocardium with or without involvement of the aortic mitral and pulmonary valves. The evidence of ischemia, scarring and infarction of heart muscle is frequently encountered in these patients even in youth. Members of such hypercholesterolemic families often exhibit symptoms and signs of heart disease at an early age. Angina pectoris is frequent and was noted in one child at the age of four. Several sudden deaths in children have been recorded.

In idiopathic familial hyperlipemia the deposit of lipids may not be limited to the formation of superficial xanthomas. Hepatomegaly, splenomegaly and enlargement of lymph nodes have been recorded. Foam cells have been found in biopsy specimens of the liver, spleen, lymph nodes and bone marrow. Abdominal pain variously ascribed to acute swelling of the liver and spleen and to pancreatitis has been frequent. Glycosuria of mild degree not influenced by the administration of insulin has also been reported. A relationship of familial hyperlipemia to atherosclerosis has been less firmly established because of the paucity of autopsies. Premature coronary atheroma has been observed and recent reports have emphasized the coincidence of angina pectoris and myocardial infarction. The single autopsied case in an infant failed to show deposit in arteries. Recent reports of idiopathic familial hyperlipemia, however, have emphasized the coincidence of angina pectoris and myocardial infarction.

**Treatment.** In familial hypercholesterolemia the course of the disease and the development or persistence of superficial xanthomas are but slightly influenced by therapeutic measures. It cannot be shown that the cholesterol concentration of the blood is materially diminished by removing cholesterol from the diet. Even low fat, low caloric diets seem to have little effect on the chemical constitution of the blood. The administration of estrogens in most cases is followed by changes in the direction of normal plasma values. In no case of xanthomatosis, however, has estrogen accomplished complete restoration of a normal pattern.

In acquired hypercholesterolemia the chemical defects of the plasma as well as the xanthomatosis may be favorably influenced by specific measures. This has been particularly dramatic with the use of in-

sulin in diabetic xanthomatosis and with the administration of thyroid substance in the rare cases in which xanthomas develop in the course of myxedema.

The possibility of modifying conditions in essential familial hyperlipemia offers more encouragement. In this condition it appears that neutral fat accumulates in the blood partly because of a delay in the removal of metabolism of ingested fat. Spacing of fat ingestion with restriction for intervals of 24 hours or more has in some cases produced material reduction in the concentrations of neutral fat in the plasma. The administration of insulin is successful in controlling the hyperlipemia of diabetes but is ineffective in idiopathic familial hyperlipemia.

### Carcinoid Syndrome

#### (Carcinoidosis)

Carcinoid (argentaffinoma) is now known to be an endocrine tumor which produces the pharmacologically active agent serotonin (5-hydroxytryptamine). Lemberck was the first to find large amounts of serotonin in both primary and metastatic carcinoid tumors. At the same time (1953) Waldenstrom and others described a bizarre clinical syndrome in patients with metastatic (malignant) carcinoid. The various manifestations of the syndrome including cyanosis, flushing, asthma, diarrhea and valvular heart disease appear to result from secretion of serotonin by the tumors and a disturbance in the metabolism of tryptophan. Over 100 cases of this disorder have been diagnosed since the original descriptions.

**Morbid Anatomy** Malignant carcinoid usually develops from a small primary lesion of the ileum. Hepatic metastases are found in advanced cases and ovarian metastases are frequent in the female. More distant metastasis may occur particularly to lung and bone. The tumors are yellow in color, firm on section and consist of epithelial cells set in a fibrous stroma. Intracellular granules giving the chromaffin-argentaffin reactions reflect origin of the tumor from the enterochromaffin cells of the intestinal mucosa.

Associated pathology is found primarily in the skin and right side of the heart. Greatly dilated capillaries and small veins are seen in the skin representing telangiectasia during life. Fibrosis of the right atrial and ventricular endocardium may involve the valve leaflets and chorda tendineae to produce pulmonic stenosis, tricuspid stenosis and tricuspid insufficiency alone or in combination. Cardiac involvement has not been observed in the absence of hepatic metastases.

**Clinical Features** A series of baffling illnesses extending over a period of years is typical coinciding with slow growth of the tumor. Current concepts are derived largely from study of advanced cases. The clinical features may be listed as follows:

**Vasomotor** The most common and often the earliest manifestation is paroxysmal erythematous flushing of the face and neck. Remarkable changes in color may be observed within a few minutes ranging from bright red to violaceous to blanching white. Facial and periorbital edema, tachycardia, hypotension and increased respiratory and intestinal distress may occur with severe flushing. Precipitating stimuli include emotional upsets, defecation, physical activity and manipulation of the tumors. After several years, milium and gross telangiectasia may develop and give an appearance of cyanosis in the absence of arterial O<sub>2</sub> unsaturation.

**Gastrointestinal** There is usually a long history of abdominal discomfort in association with recurrent attacks of diarrhea. Nausea and vomiting develop with frequent or prolonged flushing. Hyperperistalsis is often apparent at the bedside. Although the primary tumor is usually silent, hepatic metastases frequently undergo necrosis leading to episodes of abdominal pain with fever and leukocytosis. The hepatomegaly may become massive but hepatic function as measured by the usual tests is often well preserved and alterations in the tests are nonspecific. An increased incidence of peptic ulcer also has been noted.

**Cardiopulmonary** Cardiac involvement is a late manifestation and occurs in about 50 per cent of far advanced cases. Right heart failure may supervene in association with pulmonary and tricuspid valve lesions. However dependent edema is common even in the absence of cardiac disease. Clinical and laboratory findings relating to the heart are comparable to those seen in similar valvular lesions of rheumatic or congenital origin and vary with the severity of involvement. Some patients have attacks of dyspnea and wheezing indistinguishable from bronchial asthma. Others experience constricting sensations in the chest and recurrent paroxysms of coughing.

**Nutritional** Loss of weight occurs intermittently but is progressive. Cutaneous lesions of pellagra have been encountered in several cases. Hypoalbuminemia is a frequent finding.

**Pathological Chemistry and Physiology**  
The major depot of serotonin in the body is the gastrointestinal mucosa. Smaller amounts are found also in the brain and blood platelets. This amine is derived from the essential amino acid tryptophan and is metabolized to 5-hydroxyindoleacetic acid (5HIAA) which is excreted in the urine (see Fig 71). In patients with malignant carcinoid the tumor is the major body depot of serotonin and generally contains 10 to 30 mg per gm. Blood levels of serotonin are elevated to 0.5 to 3.0 micrograms per ml compared to normal values of 0.1 to 0.3 microgram per ml and the urinary excretion of 5HIAA is greatly elevated usually being 50 to 600 mg per day compared to 20 to 10 mg per day in normal persons. As much as 60 per cent of dietary tryptophan may be deviated into the serotonin pathway by the tumor.

Fig. 21

whereas normally only about 1 per cent is metabolized in this manner. This diversion of tryptophan leaves less available for the formation of other substances such as niacin and protein.

The pharmacological effects of serotonin on smooth muscle account for the vaso motor disturbances, hyperperistalsis and bronchoconstriction. The acquired lesions of the heart are probably also on a chemical basis but have not been produced experimentally. Because of the abnormality of tryptophan metabolism in patients with malignant carcinoid, decreased food intake and loss of nutrients by diarrhea which would not significantly affect a normal person may lead to the development of pellagra and protein deficiency.

**Diagnosis.** The syndrome is easily recognized when fully manifest. However, it is important to realize that any single sign or symptom may be the sole or predominant evidence of functioning carcinoid. The diagnosis is established by a simple qualitative test for increased excretion of 5HIAA in the urine. Values above 15 mg per day are sufficiently high to suggest the diagnosis of carcinoid. The ingestion of a few bananas may result in false positive chemical diagnosis since a single banana contains about 4 mg of serotonin.

**Prognosis.** Patients with this disorder succumb eventually to nutritional, cardiac or hepatic failure.

**Prevention and Treatment.** Surgical extirpation of tumor offers the only definitive means of ameliorating symptoms and prolonging life. Early diagnosis and inspection of the terminal ileum during routine abdominal surgery with excision of primary lesions offer the best means of prophylaxis. An adequate diet and vitamin supplements including niacin are indicated. Other medical therapy constitutes the treatment of symptoms and complications. Serial measurements of urinary 5HIAA afford a unique method of following progression of the disease or judging the effectiveness of attempts to eradicate the tumor.

## The Lipomatoses

The term "lipomatoses" refers to a group of unrelated local abnormalities in fat distribution to be distinguished from systemic disorders of fat metabolism. The most common of these abnormalities are lipomas, slow growing and ordinarily discrete single or multiple benign tumors arising usually from the subcutaneous fat of the shoulders, back, neck or proximal half of the extremities. If tender, large or unsightly, the lipomas may be excised. Interstitial visceral thoracic, abdominal and nervous system lipomas also occur. A painful form of multiple circumscribed subcutaneous lipoma or neurolipoma is designated *Dercum's disease* or *adiposis dolorosa*. *Sclerosing lipogranuloma* is the result of trauma, local ischemia and necrosis of fat deposits with infiltration and fibrosis of the surrounding tissue. Localized atrophy or spongy hypertrophy of fat may occur at the site of insulin injections, *insulin lipodystrophy*.

Lipomatosis may be more diffuse symmetrically involving the neck ("fat neck", *Madelung's neck*) to form large disfiguring masses which sometimes extend down over the shoulders and arms or are occasionally segmentally distributed on the thorax. In women a common form of symmetrical subcutaneous deposition of excessive fat in the buttocks and legs with more or less dependent edema has been designated *lipedema*.

**Progressive Lipodystrophy (Barraquer-Summons Disease).** Progressive lipodystrophy is a disorder characterized by symmetrical and slowly progressive loss of subcutaneous fat from the face; in more severe cases also from the neck, arms, thorax and abdominal wall with preservation or increase in the fat of the lower part of the body. Extensively affected patients present a bizarre appearance of emaciation of the upper portions of the body particularly of the face with contrasting pronounced

obesity of the hips buttocks and legs The cause of the disease is not known

The onset commonly is between the ages of four and eight young girls being chiefly affected but the disorder may develop in adults The rate of progressive involvement varies from one or two years to over a decade but arrest may occur at any stage The muscles hair and sweat glands of affected areas are spared Apart from weight loss and emotional disturbances attending disfigurement there is usually no associated abnormality or incapacity There is no known treatment

**Intestinal Lipodystrophy (Whipple's Disease)** As described by G H Whipple in 1907 this disorder is characterized by gradual loss of weight and strength stools consisting chiefly of neutral fat and fatty acids indefinite abdominal signs and a peculiar multiple arthritis The underlying pathological findings include a striking lipogranulomatosis of enlarged mesenteric lymph nodes and the presence of large foamy macrophages filled with an unidentified glycoprotein in the tunica propria of the small intestine cystic dilatation of the mesenteric lymphatics may also occur These morphological abnormalities induce or reflect a malabsorption syndrome resembling sprue

The etiology is obscure The impairment in intestinal absorption particularly of fat at first suggested a metabolic or morphological defect specifically of the cells of the intestinal mucosa but the accompanying widespread systemic involvement and the presence of an abnormal glycoprotein in the serum have subsequently suggested the possibility of a more general metabolic defect Puute and Tesluk have described familial occurrence of the disorder and imply genetic transmission

The disease has a predilection for males usually between the ages of thirty and sixty five The onset is insidious usually with diffuse abdominal discomfort and in intermittent diarrhea the stools later becoming bulky frothy and foul smelling and containing large amounts of neutral fat and fatty acids Sometimes the disease is ushered in with bouts of migratory polyarthritis which may indeed dominate the picture for several years Intermittent fever hypotension hypochromic anemia lymphadenopathy chronic cough hypocholesterolemia hypoalbuminemia and edema are common accompaniments Ascites (some times chylous) and fibrous polyserositis may occur Occasionally there is pronounced pigmentation of the skin simulat-

ing Addison's disease in the late stages tests for adrenocortical function however give essentially normal results X rays show a typical "deficiency pattern" of the small bowel The glucose tolerance curve is normal or flat free acid in the gastric contents is diminished or absent pancreatic secretion is preserved

The diagnosis is most securely established by intestinal biopsy but peripheral node biopsy may suffice to demonstrate nests of macrophages giving a positive periodic acid Schiff stain indicative of abnormal deposits of glycoprotein The serum mucoprotein level may be substantially increased

The course is protracted and with spontaneous remissions characterized by progressive weakness and weight loss terminating in extreme debility and death usually within five years of onset Treatment is supportive and symptomatic Corticotropin and corticosteroids induce amelioration of symptoms in many cases and should be given a protracted trial

**Relapsing Febrile Nodular Nonsuppurative Panniculitis (Weber Christian Disease)** This disorder in its most typical form is characterized by recurring febrile bouts associated with the appearance of crops of subcutaneous fatty nodules which are usually tender The cause of the disease is not known Necropsy findings indicate that the underlying abnormality may be not an entirely local disturbance confined to the panniculus but a more generalized disorder of fat metabolism Kennedy and Murphy believe that the changes in adipose tissue are due to ischemia secondary to thrombosis or endarteritis of small vessels with subsequent necrosis of fat cells and infiltration by macrophages and mononuclear cells Weber found that administration of iodides could produce the manifestations in susceptible persons but in most cases there is no history of exposure to iodides Similar manifestations have been produced by trauma which may be minimal and by repeated subcutaneous injections and local application of cold There is no convincing evidence of an infectious etiology

The earliest morbid changes in the panniculus appear to be accumulations of lipophages often associated with periarteritis and arteriolitis Central areas of softening due to fat necrosis and edema then appear along with increased numbers of fat laden macrophages lymphocytes large mononuclear cells and sometimes many polymorphonuclear cells Late lesions show a decrease in necrotic material and inflam-

matory cells with more or less fibrous tissue replacement. Similar changes may involve fat deposits in addition to those in the subcutaneous layers—for example pancreatic adipose tissue and omental mesenteric peripelvic periadrenal and epicardial deposits. Moreover extensive fatty infiltration and central necrosis of the liver with hemorrhage occur apparently quite regularly. Fatty and hydropic degeneration of the pancreas and adrenal cortex have been described as have fat emboli in the lungs.

The disorder has been described in patients ranging in age from two to sixty-four years. Females appear to be somewhat more frequently affected. Prodromal symptoms of malaise, fever, sore throat or arthralgia often precede the onset of fever and the appearance of nodules. Leukopenia is the rule and may be marked although some cases have shown leukocytosis. Joint and muscle pains sometimes are generalized and severe.

The nodules appear most frequently on the thighs; they also appear on other portions of the legs on the arms and trunk but rarely on the buttocks, breast, face, hands and feet. They are usually multiple, vary in diameter from about 1 to 10 cm and are apt to be tender and sometimes spontaneously painful. The overlying skin may be inflamed. A nodule occasionally may rupture, exuding turbid, fatty material which yields no bacterial growth on culture. Internal fat deposits also may be involved, giving rise to obscure febrile episodes and abdominal pain.

The course is protracted and marked by remissions and exacerbations. There is no satisfactory treatment although improvement of uncertain duration has been ascribed to sulfapyridine and penicillin. ACTH and cortisone have been tried but have proved generally disappointing.

## Amyloidosis

**Definition.** Amyloidosis is a disorder characterized by the deposition in various tissues of amyloid, a difficultly soluble protein containing sulfated mucopolysaccharides of which the most distinctive is heparin sulfate (Karl Meyer). Variants of amyloid are often referred to as paramyloid.

No satisfactory classification of the several categories of amyloidosis is yet possible. The most commonly employed scheme lists primary (systemic) amyloidosis (which occurs in familial and sporadic forms), secondary (parenchymatous) amyloidosis, amyloidosis associated with multiple myeloma and localized amyloid tumors. The distinction between primary and secondary amyloidosis however often is not sharp because of difficulties in evaluating the provocative role of minor suppuration (as in the lungs or kidneys) and the overlapping of organ and tissue distribution. Further, some cases designated primary amyloidosis probably are instances of occult multiple myeloma. In any event, primary amyloidosis presumably is a manifestation of some obscure underlying metabolic disorder and in this sense is really "secondary."

**Etiology.** Secondary amyloidosis classically is related to chronic suppuration, notably protracted tuberculous involvement of the lungs or bone, chronic osteomyelitis due to pyogenic organisms, lung abscess or bronchiectasis. It occurs also as a complication of many other conditions associated with tissue destruction and infection including malignant tumors (notably hypernephroma), Hodgkin's disease, chronic ulcerative colitis and regional ileitis with fistulation, rheumatoid arthritis, chronic pyelonephritis and paraplegia with suppurating decubitus ulcers and urinary tract infection, occasionally also in association with plasmacytosis and hyperglobulinemia in drug sensitivities. In recent years, owing to the advent of effective antibiotics, these latter associations with secondary amyloidosis have indeed superseded in frequency the classic occurrence with tuberculous and pyogenic infections of lung and bone.

In view of the protein nature of amyloid and its not infrequent appearance in animals with prolonged hyperglobulinemia due to hyperimmunization or sodium caseinate administration, some investigators have related secondary amyloidosis to a disturbed protein metabolism associated

with suppuration and tissue breakdown. The evidence for this relationship is not clear however and further investigation is needed.

**Primary systemic amyloidosis** is not or directly associated with chronic infection or other overt disorder and its origin remains obscure. The familial form is characterized by the presence of an abnormal  $\alpha$  globulin component in the plasma which appears to be a lipoprotein (Rukavina *et al.*) It has been suggested that the deposits of amyloid in the tissues may be derived from this and other abnormal proteins which have been discovered in the plasma of patients with amyloidosis.

The incidence of amyloidosis in multiple myeloma varies in different series averaging about 15 per cent. Magnus Levy stressed derivation of the amyloid from Bence Jones and related abnormal proteins in multiple myeloma but most cases with extensive amyloidosis do not have conspicuous hyperglobulinemia.

**Localized amyloid tumors** occur as isolated growths chiefly in the larynx, trachea and bronchi. A rare form limited to the skin has been described (lichen amyloidosis). There is no clue as to etiology.

**Morbid Anatomy.** The spleen, kidney, liver and the cortex of the adrenal glands are the most common sites of *secondary amyloidosis*; these organs characteristically being enlarged and firm, the involved areas homogeneously infiltrated and of waxy pallor. Lymph nodes, pancreas, gastrointestinal tract, prostate, thyroid and other organs may also show involvement. Microscopic examination indicates a predilection for the walls of capillaries and arterioles, earliest deposition occurring beneath the endothelial cells in arterioles extending into the media. In the spleen, infiltration of amyloid begins in and around the malpighian bodies giving rise to the typical sago spleen; in the liver, earliest involvement is subsinusoidal; in the kidney, amyloid first appears subendothelially in the glomerular capillaries beneath the epithelium of Bowman's capsule and occasionally in the tubular epithelium beneath the basement membrane. In all organs, accumulation and expansion of these deposits in blood vessels and reticulum fibers lead to compression and atrophy of the tissue parenchyma until in advanced cases much of the substance may be composed of amyloid.

Iodine (Lugol's solution) imparts a deep brown color to secondary amyloid deposits upon addition of sulfuric acid, a dark blue

color forms hence Virchow's designation of the substance as amyloid (starchlike). Congo red and eosin give an intensely pink color; van Gieson's stain a yellow or brownish color; periodic acid-Schiff stain a bright red. Amyloid stains metachromatically with methyl violet and crystal violet. These reactions are consistently obtained in secondary amyloidosis as encountered in man and upon them rests the ultimate diagnosis.

In *primary systemic amyloidosis* the sites of predilection are cardiac, skeletal and smooth muscle, initially involving the interstitium and progressively compressing muscle fibers with atrophy and replacement by amyloid. The myocardium characteristically is extensively involved with cardiac enlargement. Macroglossia is common. The smooth muscle of many medium-sized and small blood vessels throughout the body is usually selectively involved. Skeletal musculature including the diaphragm and the smooth muscle of the gastrointestinal tract also the skin may be diffusely affected. The liver, spleen, kidney, adrenal gland, lung, lymph nodes, peripheral nerves, joints, bone marrow and other tissues are more commonly involved than is generally stated. The skin may be diffusely infiltrated, particularly about the head and neck, hands and nails, often with local hemorrhages or translucent papules and plaques of the skin and mucous membranes may appear. Staining reactions with iodine, Congo red and the metachromatic dyes are often erratic, apparently because of variations in chemical structure.

In distribution and erratic staining characteristics the amyloid deposits in *multiple myeloma* resemble primary more than secondary amyloidosis.

**Symptoms and Signs.** The onset and progression of amyloid disease are insidious. In *secondary amyloidosis* the clinical picture ordinarily is overshadowed by the inciting disease. Amyloid disease of the kidneys is most apt to become clinically apparent with marked albuminuria, cylindruria, edema, hypoalbuminemia and more or less pronounced hypercholesterolemia—in severe cases the full-blown nephrotic syndrome. Obliteration of glomeruli and subsequently of entire nephrons may become extensive enough to cause hypertension and uremia terminating as a contracted kidney. Diffuse involvement of the liver may be suggested by hepatomegaly with a firm, blunt, smooth, nontender liver edge. Ascites may occur but jaundice and significant hepatic failure are rare. In the author's experience there may be brom-

matory cells with more or less fibrous tissue replacement. Similar changes may involve fat deposits in addition to those in the subcutaneous layers—for example pancreatic adipose tissue and omental mesenteric peripelvic periadrenal and epicardial deposits. Moreover extensive fatty infiltration and central necrosis of the liver with hemorrhage occur apparently quite regularly. Fatty and hydropic degeneration of the pancreas and adrenal cortex have been described as have fat emboli in the lungs.

The disorder has been described in patients ranging in age from two to sixty-four years. Females appear to be somewhat more frequently affected. Prodromal symptoms of malaise, fever, sore throat or arthralgia often precede the onset of fever and the appearance of nodules. Leukopenia is the rule and may be marked although some cases have shown leukocytosis. Joint and muscle pains sometimes are generalized and severe.

The nodules appear most frequently on the thighs; they also appear on other portions of the legs, on the arms and trunk, but rarely on the buttocks, breast, face, hands and feet. They are usually multiple, vary in diameter from about 1 to 10 cm and are apt to be tender and sometimes spontaneously painful. The overlying skin may be inflamed. A nodule occasionally may rupture, exuding turbid, fatty material which yields no bacterial growth on culture. Internal fat deposits also may be involved, giving rise to obscure febrile episodes and abdominal pain.

The course is protracted and marked by remissions and exacerbations. There is no satisfactory treatment, although improvement of uncertain duration has been ascribed to sulfapyridine and penicillin. ACTH and cortisone have been tried but have proved generally disappointing.

## Melanosis and Melanuria

The brown or black pigments called melanins are high molecular polymers of oxidation products of ortho-dihydroxyphenol derivatives. They are formed for the most part from tyrosine which is oxidized by tyrosinase to dihydroxyphenylalanine ("dopa") then to a red quinone designated hallachrome which is converted to indole quinones and finally polymerized to form melanins.

The melanins are elaborated by melanoblasts normally present in the skin and other organs. Abnormal deposition of melanins is called *melanosis* and should be distinguished from darkening of the skin or membranes due to deposition of silver (argyria), bismuth (bismuthia), iron (hemosiderosis), bile pigments or other substances. Darkening of the urine due to excretion of melanin is termed *melanuria*.

Increased pigmentation of the skin or mucous membranes need not of itself have any deleterious connotation as for example the tanning or freckling of the skin after exposure to ultraviolet rays or the pigmentation particularly of the face (chloasma gravidarum) commonly accompanying pregnancy. Darkening of the skin also occurs after radiation therapy and after prolonged mechanical irritation (scratching due to vermin infestation or to other causes of pruritus) or prolonged administration of certain chemicals notably arsenicals.

The chief importance of diffuse or localized melanosis lies in its frequent association with a variety of significant disorders. The melanosis of Addison's disease for example may provide an important clue to diagnosis in this disorder; the decrease in corticosteroid secretion leads to augmented release of melanocyte stimulating hormones (intermedin) by the pars intermedia of the pituitary gland. The blue-black ears of ochronosis are characteristic of that disorder. Vitamin deficiencies in pellagra and sprue not infrequently are accom-

panied by increased pigmentation of the skin particularly of the exposed areas. In neurofibromatosis (von Recklinghausen's disease) sharply defined areas of skin pigmentation characteristically are present even if subcutaneous nodules are inconspicuous or absent and are an aid in diagnosis. Similar pigmented areas usually more irregular in configuration are apt to develop in involved neurodermal segments in fibrous dysplasia of bone. *Familial polyposis of the small intestine* with early neoplastic degeneration is sometimes identifiable by the presence of melanosis of the skin about the mouth and nose with discrete areas of pigmentation of the buccal mucous membranes and on the hands. Diffuse melanosis of exposed areas of skin may be observed also in association with porphyria, systemic lupus erythematosus, dermatomyositis and primary biliary cirrhosis.

Melanosis and melanuria occur in association with malignant melanomas. These tumors usually arise from a pigmented flat hairless mole or from the uveal tract and metastasize widely and rapidly. They are apt to elaborate melanin pigments in considerable quantity, many however as colorless precursor melanogens. In addition to pigmented metastases there may be diffuse melanosis of the skin and other organs. In such instances the urine may contain a sufficient quantity of pigment to take on a brown or black color when voided, often however the urine turns dark only upon standing because of the oxidation of melanogens. Addition of ferric chloride gives a dark brown or black precipitate; bromine water forms a yellow precipitate which darkens gradually. The dark color of the urine due to the presence of melanins should be readily distinguishable from that of hemoglobinuria, porphyria and alkaptonuria by these and other appropriate tests.

*Acanthosis nigricans* is characterized by the appearance of soft velvety brownish to black verrucous plaques of cutaneous folds characteristically present in the axillae but sometimes also involving the external genitalia, perianal area, nipples and umbilicus and occasionally affecting the mucous membranes. There may be hyperkeratosis of the palms and soles with papillomatous elevations elsewhere often associated with local loss of hair. The juvenile form usually present at birth is benign. Onset after the age of forty is associated in approximately one half of the cases with malignancy preponderantly of the

sulfalein retention and marked increase in serum alkaline phosphatase apparently due to obstruction of intrahepatic excretory channels. The spleen is usually only moderately enlarged however the diffuse type of splenic involvement results in marked splenomegaly occasionally with rupture. Manifestations of Addison's disease if present ordinarily are due to associated tuberculosis which can usually be recognized roentgenographically by local calcification. Amyloidosis of the gastrointestinal tract may be associated with chronic diarrhea.

Whereas secondary amyloidosis may develop at any age depending on the underlying disease primary systemic amyloidosis occurs usually between the ages of forty and eighty. Males are more commonly affected than females. The presenting symptoms are usually those of intractable congestive heart failure with dyspnea, edema and fluid in serous cavities. Macroglossia may be striking with dysarthria and dysphagia. Asthenia and weight loss are the rule in late stages. Deposits in the skin may simulate scleroderma or myxedema. Hypertension, lymphadenopathy, pains in joints and extremities and purpura occur. An occasional feature is the carpal tunnel syndrome. In some cases the distribution of amyloid deposit is predominantly in the liver, spleen and kidneys, as in secondary amyloidosis with corresponding symptomatology.

In the familial form of primary systemic amyloidosis which is compatible with long life the presenting symptoms are apt to be neuropathies involving the upper and lower extremities. Associated with these there may be amyloid deposits in the skin, liver and spleen, cardiac enlargement and impaired function, disturbances in ocular movements and involvement of the gastrointestinal tract.

The clinical manifestations of amyloidosis associated with multiple myeloma may be inconspicuous in relation to those of the underlying disorder but occasionally dominate the picture. Ordinarily the distribution of the deposits and the corresponding symptomatology resemble primary systemic amyloidosis and are as polymorphic in clinical expression. Predominant hepatosplenomegaly and amyloidosis of the kidney may occur.

Localized amyloid tumors of the larynx may cause hoarseness and if large may result in obstructive dyspnea. They can be visualized by laryngoscopy or bronchoscopy and identified by histological examination of biopsy specimens.

**Diagnosis.** Amyloidosis should be kept in mind as a possible complication of the suppurative diseases with which secondary amyloidosis is associated. Development of marked albuminuria or the nephrotic syndrome in the course of these diseases should raise the question of amyloid nephrosis. Needle biopsy of the liver or kidney may secure the diagnosis. Gingival biopsy is often helpful but does not disclose amyloid deposits in many cases.

The Congo red test which depends upon rapid removal of the injected dye from the blood as a result of selective adsorption by amyloid deposits is a useful but sometimes uncertain diagnostic method. Taran and Eckstein recommend standardization of the procedure by use of 1 ml of a 1 per cent aqueous solution per 10 pounds of body weight. Adsorption of at least 90 per cent of the dye in one hour constitutes a positive test and good evidence for diffuse amyloidosis. A smaller percentage of dye is removed in nonamyloid cases or when the amyloid deposits are small or of a type that does not readily adsorb the dye.

Recognition of primary systemic amyloidosis is difficult; the cardiac manifestations simulating constrictive pericarditis or arteriosclerotic heart disease. Macroglossia may suggest the diagnosis which depends upon biopsy and even then may be uncertain because of erratic staining properties of the amyloid. The Congo red test frequently is negative or inconclusive for the same reason. In the hereditary form a familial history may suggest the diagnosis.

**Prognosis and Treatment.** The average period of survival from onset of symptoms in nonfamilial primary systemic amyloidosis is about three years. Death is usually due to intractable cardiac failure. Treatment is symptomatic.

In secondary amyloidosis therapy is aimed at the underlying suppurative disorder. Control of suppuration by treatment with antibiotics has a prophylactic effect on complicating amyloidosis as indicated by a reduction in incidence in recent years.

## Hemochromatosis

**Definition.** Hemochromatosis (iron storage disease) is a chronic disease characterized by the deposition of iron in body tissues with eventual fibrosis and functional insufficiency of those organs severely involved. Depending on the manner in which excess iron deposits are produced hemochromatosis may be characterized as idiopathic, dietary, or due to blood transfusion.

**Morbid Anatomy.** At autopsy the unique finding in hemochromatosis is a bronze pigmentation of body tissues due to widespread deposition of hemosiderin. These iron deposits are heaviest in the liver but are also prominent in the reticuloendothelial tissue, endocrine glands, striated muscle, and skin. The liver is sclerotic and usually large (average weight 2400 gm.). Fibrosis of the pancreas and of lymph nodes containing large amounts of iron is commonly though not invariably found. Iron deposits within the heart muscle cells are of particular significance because of the associated cardiac dysfunction.

**Pathogenesis and Pathologic Physiology.** Recently many of the unusual features of idiopathic hemochromatosis have been clarified through isotopic studies of iron metabolism. Excretion of iron in man has been shown to be negligible; absorption rather than excretion controls the amount of body iron. When tissue iron stores are adequate a mucosal block prevents excessive iron absorption. In idiopathic hemochromatosis this is for unknown reasons ineffective, and a great surplus of iron accumulates. Because the iron accretion is gradual, symptoms do not usually appear

until the patients are beyond thirty-five years of age (70 per cent between the ages of forty to sixty years). The pre-dominance of hemochromatosis in the male (about 95 per cent) is understandable when one considers the difference in iron balance between the two sexes. The male is unable to rid himself of iron once it is absorbed, but the female does so continually through menstruation and pregnancy.

Tissue iron in idiopathic hemochromatosis represents iron absorbed and stored in a form available for hemoglobin formation rather than a product of abnormal tissue metabolism. The liver is the shock organ for such storage and may contain up to 50 gm. of iron in the form of ferritin and hemosiderin. As the storage capacity of the liver is exceeded, iron spills over into other receptor tissues, particularly into the endocrine glands and skin. The serum iron becomes elevated and saturates the iron-binding protein of the serum which transports it. Liver fibrosis is thought to be produced by the large amounts of iron which accumulate in the periportal areas of the liver lobule. The defect in absorption is not limited to iron; since other metals may be found in excess in the tissues, alcoholism and dietary deficiency do not figure as essential factors in this disease as they do in Laennec's cirrhosis, although a history of excessive alcohol intake has been noted in roughly one third of the patients with idiopathic hemochromatosis. Enough data are available to indicate a significant familial and hereditary tendency. Idiopathic hemochromatosis must be considered a rare disease, although it undoubtedly occurs more frequently than the reported autopsy incidence of 0.003 to 0.08 per cent.

It is increasingly apparent that transfusion hemochromatosis may be pathologically indistinguishable from the idiopathic type and may also present evidence of damage to the liver, heart, and pancreatic islets. Since initial deposition of iron from transfused red cells is in the reticuloendothelial system, there continues to be discussion of histological differences in iron distribution between these two types of iron storage disease. Time and perhaps other factors such as the level of erythropoietic activity may play a role in redistribution of iron. It is considered that in excess of 100 transfusions represents a potentially harmful iron load.

Patients with what may be designated dietary hemochromatosis have been reported by Gillman and his co-workers. Here

■ high dietary intake of iron ■ maintained over many years and again the pathological appearance of the liver may be similar to that seen in idiopathic hemochromatosis although other nutritional deficiencies probably play an important role in tissue damage. The prolonged oral administration of medicinal iron to the anemic patient has also been reported to lead to hemochromatosis. Recent studies suggest that the anemic patient with a hyperplastic erythroid marrow is more likely to absorb excessive amounts of medicinal iron than the patient with an acellular marrow.

**Clinical Picture** The presenting complaints in idiopathic hemochromatosis may relate to skin pigmentation, diabetes, hepatomegaly, symptoms of severe liver disease, endocrine dysfunction and heart failure.

**Pigmentation of the skin** ■ of two types. In about half of the patients there ■ an Addisonian-like bronzing due to increased melanin. In the remaining patients the skin acquires a blue gray or leaden cast as a result of iron deposition. The pigment is distributed most prominently over the genitalia, face and arms and in skin folds. Mucous membranes are involved in only about 15 per cent of the patients.

The liver is usually palpable and the spleen is also palpable in about half the cases. The enlarged liver is frequently associated with upper abdominal pain which may occasionally be excruciating and knife-like simulating biliary colic or perforated peptic ulcer. Visible jaundice is unusual. There is frequently no indication of the severe liver disease other than general body wasting. Many patients as a result of some acute illness or stress situation suffer acute liver decompensation with coma and death rapidly supervening. Hepatoma is an important complication in the older patient. Hemorrhage from a ruptured esophageal varix is less frequently encountered than it is in nonpigmentary cirrhosis and evidence of increased collateral circulation is rare. Ascites may appear as a terminal event. Sexual impotence is ■ common complaint in the late phase of the disease but may occur when the patient is otherwise asymptomatic. Testicular atrophy, loss of axillary and chest hair and occasional gynecomastia may be regarded as related to liver dysfunction.

The diabetes of hemochromatosis is mild at the onset but progressively worsens. A few patients are sensitive to insulin but a greater number are relatively resistant, occasionally requiring several hundred units a day.

Cardiac deposits of hemosiderin are frequently associated with arrhythmias and congestive heart failure which responds poorly to conventional therapy. A moderate macrocytic anemia ■ found only in the late stage of the disease. In the early phases the hemoglobin concentration is apt to be above normal.

**Diagnosis** There is little difficulty in recognizing this disease in ■ patient with the classic tetrad of skin pigmentation, liver disease, diabetes and cardiac failure. A high index of suspicion in the presence of any two of these four cardinal findings will frequently lead to the diagnosis. Laboratory studies center around the demonstration of excessive iron stores and second of hepatic, pancreatic or cardiac disease. When liver disease is suspected a needle biopsy is the most conclusive diagnostic procedure but its use ■ restricted because of the risk involved. (In this type of liver disease abdominal exploration and direct biopsy are even more hazardous.) An elevated serum iron and saturation of the iron binding capacity of the serum are the most useful special laboratory findings in the demonstration of iron excess. Other tests employed in order of their usefulness are examination of urinary sediment, examination of the sternal marrow for hemosiderin, skin biopsy and biopsy of gastric mucosa. Iron in the skin is of diagnostic significance when found in the epithelial cells of the sweat glands.

**Prognosis and Treatment** The average duration of life after diagnosis has been lengthened from the eighteen months reported by Sheldon in 1935. Since the advent of insulin, diabetes has been adequately controlled in the majority of cases. In patients under forty most fatalities are ascribable to cardiac failure; in those between the ages of forty and sixty hepatic failure and infection may cause death and in patients over sixty a hepatoma may develop.

Supportive therapy in idiopathic hemochromatosis ■ directed at management of the liver disease and when it is present, diabetes. A high caloric diet (50 calories per kg) and supplementary B vitamins appear to be beneficial. Insulin should be prescribed as required with this diet. It would seem wiser in view of the liver disease to allow some glycosuria rather than risk hypoglycemia.

On the assumption that iron deposits are chiefly responsible for tissue damage, specific therapy should be directed toward removal of iron through phlebotomy. In pa-

tients with idiopathic hemochromatosis weekly phlebotomies of 500 ml are well tolerated. Each phlebotomy removes 200 to 250 mg of iron from the blood which is replaced by an equivalent amount of iron from the tissue stores. In contrast to normal persons who rapidly become anemic on this regimen patients with idiopathic hemochromatosis maintain their red cell hematocrits at levels between 35 to 45 per cent. Over a period of two to three years the bulk of the iron deposits in the tissues will be mobilized for hemoglobin production and removed by bleedings.

The reversibility of hemochromatosis will depend on the amount of tissue damage present before the therapy is undertaken and the extent to which the iron *per se* is responsible for tissue damage. Experience with this form of treatment is sufficiently encouraging to indicate its routine usage but as yet is too limited to permit evaluation of its long term effect on the course of the disease.

### Agammaglobulinemia

**Definition** This is a syndrome characterized by marked deficiency of plasma gamma globulins, impairment of antibody formation and frequent severe infections.

**Etiology and Pathogenesis** The hypogammaglobulinemias may be divided into two main groups on the basis of their pathogenetic mechanism (Table 1). In the primary group comprising the true agammaglobulinemias or antibody deficiency syndromes the deficiency is due to a diminished rate of synthesis. This is associated with morphological changes in the lymphoid tissues and failure of plasma cells to develop in the lymphoid follicles and bone marrow and of antibodies to appear in the blood after antigenic stimulation. This alteration in structure and function of the lymphoid system may have various causes. In the secondary group hypogammaglobulinemia is due to loss of gamma globulins from the body or their increased catabolism while synthesis remains relatively normal. In this group other proteins such as albumin are affected. Antibody formation may occur and infection is less

of a problem except in the nephrotic syndrome.

**Symptoms and Signs** The outstanding clinical manifestations are recurrent severe infections usually due to the common pyogenic bacteria. These differ from infections in normal persons only by their frequency and seriousness. Upper respiratory tract infections with sinusitis, conjunctivitis, otitis media and repeated episodes of pneumonia are particularly common. Furunculosis, bacteremia, meningitis, septic arthritis and gastrointestinal disorders with a spruelike picture in the adult may also occur.

Tonsils, adenoids, thymus and lymph nodes are small in congenital cases but tender regional lymphadenopathy may develop with infection. Some acquired cases have similar findings whereas in others persistent lymphadenopathy and splenomegaly may be noted.

Viral infections seem to be tolerated more normally although fatal hepatitis, presumably of the homologous serum type, has been reported twice.

**Complications** are of two types: (1) suppurative with local injury from infection, bronchiectasis being most frequent; and (2) nonsuppurative including chronic arthritis observed in about one third of congenital cases and rarely dermatomyositis or scleroderma.

**Laboratory Findings** Those associated with acute infections are not unusual except that neutropenia or hyperleukocytosis are frequently observed. The agammaglobulinemic state may be recognized by study of the serum which usually reveals (a) as presumptive evidence: (1) low globulin concentration associated with normal albumin; (2) absent or very low isohemagglutinin titer; (3) low zinc turbidity value; (4) absence of specific antibodies expected from previous infections or immunizations; (b) as diagnostic evidence: (1) virtual absence of gamma globulins on electrophoretic analysis; (2) gamma globulin level below 150 mg per 100 ml by more accurate immunological methods.

**Treatment** Acute infections require intensive antimicrobial chemotherapy which should be continued until all signs of infection have disappeared. In the absence of bronchiectasis or other structural changes from preceding infections replacement therapy with human gamma globulin is quite effective in prevention of severe infections. The aim is to keep the gamma globulin level above 150 mg per 100 ml. This requires an initial dose of 0.2 gm per kg (0.6 ml per pound) and a maintenance

Table 1. Hypogammaglobulinemia

TYPE	ETIOLOGY	MECHANISM	PATHOLOGY OF LYMPHOID TISSUE	PLASMA GAMMA GLOBULINS Normal 700-1200 mg per 100 ml
PRIMARY (AGAMMAGLOBULINEMIA)				
1 <i>Transient</i> Infants (both sexes) 1-5 months	Immaturity of lymphoid tissues	Decreased Synthesis	Immature follicular structure Few plasma cells	(mg per 100 ml) <150
2 <i>Congenital</i> (Chiefly males) 4 months and older	Genetic (Sex linked recessive)		Poor follicular structure Absence of plasma cells	0-25
3 <i>Acquired</i> (Both sexes) Any age	a Destruction or replacement of normal lymphoid tissues  b Idiopathic		a Granulomatous or neoplastic infiltration of lymphoid tissues Few plasma cells ■ Variable (hyperplastic or hypoplastic) follicular structure Very few plasma cells	0-100
SECONDARY (HYPOGAMMAGLOBULINEMIA)				
1 <i>Idiopathic Hypoproteinemia</i>	Not known	Increased catabolism	Normal	200-400
2 <i>Nephrotic Syndrome</i>	Not known	a Increased catabolism ■ Loss in urine	Normal	200-300

dose of 0.1 gm per kg (0.3 ml per pound) given in single or divided doses every four weeks

## Dehydration and Fluid Balance Physiological Principles

The term dehydration as used in clinical medicine refers to a condition in which the volume of body fluids and particularly the volume of extracellular fluid is diminished. Because of the multiplicity of derangements

which may contribute to dehydration and the varying severity and chemical nature of the disturbance, each patient constitutes an individual problem in evaluation and therapy. Therefore, it is important that the principles involved in fluid and electrolyte balance be clearly understood.

The volume and the total concentration of dissolved substances in body fluid are the dimensions particularly pertinent to this consideration of fluid and electrolyte balance. The maintenance of composition with respect to specific electrolytes and the regulation of acid base equilibrium while of vital importance and not infrequently disturbed in association with dehydration, is beyond the scope of the present discussion.

**Normal Anatomy.** Water constitutes some 55 to 60 per cent of the weight of an average normal person but varies in amount inversely with the body's fat content. The plasma and the interstitial fluid of tissues, which together constitute the extracellular fluid, comprise slightly more than one third of the body water; the remainder is within cells. The cell membranes may be regarded as freely permeable to water but do not allow the free passage of strong electrolytes.

Water moves into and out of cells in response to changes in osmotic activity across the cell membranes. Water added to the extracellular compartment is rapidly distributed in the total body water. Conversely if solute to which cell membranes are impermeable is added to the extracellular fluid, water is withdrawn from cells. In each case the total concentration is ultimately uniform throughout body water.

Extracellular fluid throughout the body is a phase of fairly uniform composition in which sodium ions and their complement of anions chiefly chloride and bicarbonate constitute all but a small fraction of the solute. Intracellular fluid varies somewhat from tissue to tissue but in general contains little sodium and chloride. The major cation, potassium, is balanced probably largely by organic phosphates and the anionic groups of proteins. The disparity in electrolyte distribution across cell membranes is maintained by the metabolic activity of the cells.

**Measurement of the Volume of Body Fluid and Its Compartments.** Numerous procedures for the estimation of the volume of body water, extracellular fluid and plasma have been devised. For the most part these are clearly designed for investigative purposes and have little utility in the study and treatment of the individual patient. However, since certain generalizations concerning the behavior of body fluid compartments have been derived from studies using these techniques, it is well to be informed concerning their nature and limitations and the reservations necessary in their interpretation.

The estimation of *total body water* is usually based on the dilution principle. Satisfactory approximations can be made by determining the volume in which heavy water or antipyrine is distributed. Sufficient time must be allowed for complete distribution of the substance in body water and in the case of antipyrine to obtain an estimate of the rate of metabolic breakdown of the drug.

The volume of *extracellular fluid* has been estimated as the apparent volume of distribution of a number of substances among which are thiocyanate, chloride, bromide, thiosulfate, sulfate (labeled with  $S^{35}$ ), inulin, mannitol and sucrose. None of these substances can be considered to yield quantitatively reliable values for various reasons, including failure to remain in an exclusive extracellular position, rapid excretion so that prolonged intravenous infusion under completely stable conditions is

necessary during their equilibration in extracellular fluid and failure to become evenly distributed in extracellular fluid within a time which can reasonably be devoted to the procedure. Since *intracellular fluid* is evaluated as the difference between total and extracellular volumes, the estimate is subject to summation and magnification of the errors of the two individual determinations.

The evaluation of *plasma volume* by dilution methods is subject to variable errors due to losses of dye (or tagged albumin) from the circulating blood while estimates based on the use of tagged red cells require assumptions concerning the proportion of red cells to plasma in the body as a whole, a ratio not necessarily given by the hematocrit determined in peripheral blood.

**Normal Fluid and Electrolyte Balance and Its Regulation.** The body normally gains fluid and electrolytes from the exterior only through the gastrointestinal tract. Water is derived from the intake of liquids and from the food, both as preformed water and that obtained upon oxidation of the foodstuffs. Those electrolytes which are of major concern in fluid balance—sodium, potassium and chloride ions—are present as such in the food.

Fluid and electrolyte or both are lost to the environment through the lungs and skin and in the feces and urine. Air is inhaled at the ambient temperature and humidity and is exhaled saturated with water vapor at body temperature. Losses of water through the lungs are therefore increased by increased pulmonary ventilation and when the water content of the inspired air is low. No electrolyte is lost by this route.

Output of water through the skin in the form of evaporation or as visible sweat may vary in amount over a wide range. The salt content of sweat is appreciably lower than that of extracellular fluid and is subject to some physiological regulation, being reduced when there is a stimulus for retention of salt in the body. In the absence of visible sweating, electrolyte loss through the skin is negligible.

Although up to 10 liters of isotonic fluid are secreted into the gastrointestinal tract each day, practically all of this water and electrolyte in addition to that ingested is normally reabsorbed into the body. The feces normally contain only a minimum of water, sodium, potassium and chloride.

Since losses through lung and skin are dependent on environment and the func-

tions of respiration and temperature regulation respectively and excretion in the stools is normally negligible only the kidney can modify the output of salt and water in a manner directly subservient to the regulation of the volume and concentration of body fluids. In general the concentration of body fluids is regulated by the retention or excretion of water whereas volume is regulated by the retention or excretion of salt.

Regulation of body fluid concentration is initiated in the hypothalamus where receptors responsive to changes in the effective osmotic pressure of body fluid regulate the release of antidiuretic hormone from the neurohypophysis. Secretion is increased when osmotic pressure is high diminished when osmotic pressure is low. Antidiuretic hormone in turn increases the reabsorption of water by the renal tubules preventing the excretion of a dilute urine and facilitating the formation of urine hypertonic to plasma. The water thus conserved dilutes the body fluid reducing osmotic pressure. Since sodium salts contribute some 85 per cent of the total solute of extracellular fluid the plasma sodium concentration is an excellent indicator of the effective osmotic pressure of the body fluids except when a high concentration of some other solute to which cells are relatively impermeable (e.g. glucose) is present. Urea does not contribute to effective osmotic pressure since it permeates cells easily.

Regulation of the volume of extracellular fluid is accomplished by modification of the excretion of sodium and the anion which accompanies it. The chain of events in this homeostatic process is not clearly understood. Several contributory factors are recognized including changes in the rate of glomerular filtration and variation in the secretion of adrenal steroids which regulate sodium reabsorption by the renal tubules. Other factors are probably also involved. Normally losses or gains of sodium are not accompanied by appreciable changes in the sodium concentration of extracellular fluid since operation of the hypothalamic regulators of water loss accurately maintains the total effective osmotic activity and hence the plasma sodium concentration at normal levels. Changes in sodium balance are therefore manifested largely as changes in extracellular fluid volume and short of actual measurements of balance are detected as changes in weight and by the clinical signs of changes in extracellular fluid volume.

Regulation of the volume of intracellular fluid is poorly understood. Most variations are probably associated with (1) changes in the organic components of cells and (2) dilution and concentration of cell solutes as a result of accession of water to or loss of water from the body.

Exchanges of Fluid and Electrolyte Between Intra and Extracellular Spaces. In recent years data have been presented which have been interpreted to indicate that under the influence of certain stresses or the administration of adrenocortical hormones there may be transfers of fluid and electrolyte from the intracellular space into the extracellular fluid which are not dependent upon exchanges with the exterior or changes in the osmotic pressure of body fluids. For the most part these conclusions are based on the estimation of body fluid compartments and therefore subject to reservations on the basis of methodology. It is undoubtedly true that sodium can replace an appreciable fraction of the intracellular potassium when the body has been depleted of the latter and that the sodium is extruded when potassium is again available. It is also probable that bone can serve as a source of cation in the presence of acidosis of the extracellular fluid (and therefore can presumably accept additional cation in alkalosis). Except for these considerations it is best to regard exchanges of fluid and electrolyte between compartments of the body water as determined by the organic constituents within cells, the movement of water in response to changes in total solute in one compartment or the other and the capacity of cells to maintain with the potassium available the normal gradients of sodium and potassium across cell membranes.

Pathological Physiology. The level of intake required to maintain fluid and electrolyte balance varies widely. The minimum intake of water under normal conditions is that required to replace losses through lung and skin and to put out in a urine of maximum concentration those solutes which must be excreted. In persons with free access to water the thirst mechanism is adequate to insure sufficient intake for maintenance of the normal concentration of body fluids. In the absence of abnormal output small amounts of sodium and potassium are adequate to maintain balance and are obtained from any but the most restricted of dietary intakes. The presence of abnormal losses may of course greatly increase intake requirements.

Loss. Increases in output by any of the

normal routes as well as from the development of abnormal routes may lead to deficits of fluid and electrolyte. While generally of minor importance relative to the other disturbances it accompanies the loss of water by *evaporation* in hyperventilation is a factor which should not be neglected. The considerable losses of both water and salt which occur with profuse sweating are frequently of clinical consequence while leakage of extracellular fluid through areas denuded of skin as by burns may lead to grave disturbances of fluid balance.

The *gastrointestinal tract* is a potential source of difficulty in the maintenance of fluid balance since it is the route of normal replacement and since a large fraction of the body's extracellular fluid is secreted into and reabsorbed from it each day. Large losses of such fluid may occur with either diarrhea or vomiting the latter being complicated in that it may cut off intake. The development of fistulous connections between the gastrointestinal tract, liver or pancreas and the exterior commonly leads to very large deficits of fluid and electrolyte if adequate replacement is not undertaken.

Regulation is ultimately dependent upon *renal function* and since this function with respect to fluid and electrolytes represents the integration of a number of processes each with its intrinsic mechanism and extrarenal regulator it is subject to a number of disturbances each of which may arise from either local or nonrenal causes. The initial process in urine formation *glomerular filtration* is dependent upon the anatomical and functional integrity of the glomeruli and upon the blood pressure. The energy is thus contributed by the heart. The restriction of glomerular filtration in the face of a falling cardiac output in dehydration and shock is often quite out of proportion to the fall in blood pressure since compensatory vasoconstriction is often far more marked in the kidney than in the body as a whole. Although such reductions of glomerular filtration tend to minimize fluid output when fluid is badly needed they seriously impair the capacity to maintain the composition of body fluids and when renal vasoconstriction has been severe and prolonged function may not be restored when shock has been alleviated.

Abnormalities of water excretion leading to dehydration with increased osmotic pressure or overhydration with decreased total solute concentration result from failure of the renal tubules to reabsorb water to form a hypertonic urine or to reject water in a dilute urine. The capacity to form a con-

centrated urine is vulnerable to many insults and is often the first function to be impaired in such disorders as nephritis and hypertensive disease and one of the last to be restored following acute renal damage produced by shock or nephrotoxic agents. Far less commonly the excretion of a dilute urine is the result of a lesion in the hypothalamic hypophyseal system leading to diabetes insipidus. Whatever its cause *incapacity of the kidney to form a concentrated urine* is a common source of fluid imbalance since any interruption of intake such as may be produced by vomiting is likely to lead to rapidly developing dehydration with further impairment of renal function.

Although inability to form a concentrated urine is usually due to organic renal disease *failure to excrete a dilute urine* when body fluids are diluted is preponderantly attributable to functional nonrenal disturbances. The intrinsic capacity to form a dilute urine is often maintained after organic renal disease has led to severe limitation of concentration. However increased secretion of antidiuretic hormone which prevents the formation of a dilute urine may be produced by stimuli other than the normal one of a rise in the osmotic pressure of body fluids. Among such stimuli are a number of drugs (e.g. nicotine morphine barbiturates), emotional disturbances and operative trauma. Failure to excrete water normally is discussed more fully in the section on Hyponatremia.

Impairment of the ability of the renal tubules to reabsorb sodium is occasionally a very striking feature of renal disease (so called salt losing nephritis) but it is best to consider some *limitation of the capacity to limit loss of sodium* when intake is severely restricted as an almost constant concomitant of advanced disease of the kidney. Less commonly the tubules fail to reabsorb sodium because of failure of normal hormonal regulation (adrenal insufficiency). The loss of sodium leads to contraction of extracellular fluid volume which in turn may lead to impairment of water excretion and a fall in the sodium (total solute) concentration of extracellular fluid.

Abnormal losses of sodium with depletion of extracellular volume may also occur even though the sodium transport mechanism and its regulation are fundamentally normal when there is *massive excretion of solute* (e.g. glucose in uncontrolled diabetes) which by osmotic effect carries out increased amounts of electrolyte. This effect

is greatly increased when the solute excreted is an anion for instance the keto acid of diabetic acidosis or the chloride from ingested ammonium chloride since this must be balanced by the equivalent amount of cation. The tendency of such excretory loads to produce rapid sodium depletion is greatly magnified in the presence of renal damage with limited ability to reabsorb sodium and to form ammonia with which to replace it in the urine.

**Clinical Manifestations** The clinical manifestations of loss of fluid and electrolyte are more or less independent of the nature of the defect which produces them and in general are those of diminished extracellular fluid and circulating blood volume—weakness, anorexia, nausea and vomiting, circulatory insufficiency with failing renal function and ultimately shock and coma. When loss of water predominates over that of solute and osmotic pressure rises thirst is particularly prominent although to a lesser extent a fall in volume alone may produce an increased desire for water.

**Diagnosis** An exploration of the patient's history as to intake and output of fluid has much to contribute to the diagnosis of disorders of fluid balance and to the selection of appropriate therapy. Such an evaluation should include consideration of both the volume and the probable electrolyte content of fluids gained or lost by all of the normal and abnormal routes. Often the presumptive diagnosis of dehydration can be made and proper therapeutic measures undertaken from such consideration alone.

On physical examination the findings are largely those of diminished extracellular fluid volume—weakness and lassitude, thirst and dryness of the mouth (these particularly marked when body fluid concentration is increased), loss of skin elasticity, a sunken appearance of the eyeballs, weakness of the pulse and hypotension. In severe grades of volume loss the signs of circulatory failure may advance to frank shock which may be accompanied by stupor or coma and severe oliguria or anuria.

**Laboratory Findings** Changes in the effective concentration of body fluids are best evaluated by measurement of the plasma sodium concentration. Consideration must be given however to the concentration of other substances particularly glucose that may constitute an appreciable fraction of that solute which does not easily penetrate cells. When a flame photometer is not available for estimation of sodium

and there is no reason to suspect the presence of increased amounts of anions other than chloride and bicarbonate in the blood (as in ketosis or advanced renal insufficiency) determination of the plasma chloride and carbon dioxide content may give a useful approximation of the plasma sodium. The latter is about 10 mEq per liter higher than the sum of chloride and bicarbonate when both are expressed in mEq per liter.

There are no wholly satisfactory laboratory methods for estimating the volume of extracellular fluid. Since changes in blood volume are frequently responsible for the severe clinical manifestations of loss of extracellular volume a rough approximation of changes in plasma volume such as can be obtained from the hematocrit and from the plasma protein concentration may be useful. Only when changes from the normal are large (and usually only when the values are increased) can any weight be given to these determinations in evaluating the initial status of the patient. Thereafter short term changes in plasma volume can be followed but it should be kept in mind that a rise in plasma protein means a decrease in the fluid of plasma only if the total circulating plasma protein has not increased. Similar consideration is necessary with respect to the hematocrit and circulating red cell mass.

The level of urea or nonprotein nitrogen in the blood is useful in following the effects of dehydration on renal function. Considerable elevation of these levels may result from dehydration even if the kidneys are intrinsically normal. However the level of urea in the blood is dependent upon the rate of protein catabolism as well as on the function of the kidneys.

**Treatment** Unfortunately dehydration of clinical significance is not infrequently permitted to develop in persons under medical care because attention is devoted to the underlying problem and fluid and electrolyte balance neglected or because an adequate volume of fluid is administered but the electrolyte content is inadequate. The prevention of such disorders of fluid balance may require only nursing attention to keep up fluid intake or the addition of salt to ingested fluid or food when loss of sodium is high. When losses are too large to be compensated by oral intake or when gastrointestinal disorders render oral administration impracticable parenteral fluid therapy may be required. The regulatory capacity of the kidneys makes it easier to maintain

normal fluid balance than to correct it when depletion has progressed to impairment of renal function

When dehydration is an established problem the primary objective should be the prompt relief of circulatory insufficiency if this is part of the clinical picture. Simultaneously restitution of a normal volume and concentration of the body fluids along with correction of other complicating disturbances such as acidosis or alkalosis should be pressed as rapidly as is compatible with safety. The possibility of relieving the disorder responsible for precipitating the dehydration should not be overlooked although delay until the more serious aspects of the dehydration have been controlled may be necessary. Milder dehydration without impairment of the circulation can often be treated by increasing the intake of fluid (to perhaps 3 liters per day) and sodium chloride (to possibly 10 gm per day) by mouth.

The management of fluid balance by the parenteral administration of fluids should be guided by consideration of the volume and composition of the deficits in each of the divisions of the body fluid. In the presence of reasonably normal renal function some reliance can be placed upon the kidneys capacity to retain selectively those components needed while discarding others—provided that all of the necessary materials are supplied in sufficient quantities that the circulation is adequate for effective operation of the kidney and provided that there is not present some powerful stimulus to retain some specific body fluid component. Excesses of water or sodium for example are often retained presumably because of overactivity respectively of the hypothalamic hypophyseal system and adrenal cortex in severely ill patients or those who have recently undergone surgery despite the fact that such retention may distort volume and concentration of body fluids.

The aspect of dehydration most threatening to the well being or even the survival of the patient is the diminution in blood volume. Restitution is most rapidly accomplished by the administration of whole blood and this is the treatment of choice in severe dehydration in which shock is present or threatening. While preparation for transfusion is in progress treatment should be initiated with the administration of 1 to 2 liters of isotonic sodium chloride solution. If whole blood is not available plasma or human serum albumin (diluted with isotonic saline to contain 5 to 7 per cent protein) may be used as a substitute

and they are especially indicated when there has been extensive exudation. However the danger of hepatitis from pooled human plasma is to be weighed against the expected benefits.

Milder abnormalities of volume concentration and acid base balance can be controlled entirely by the administration of isotonic saline solution leaving to selective renal activity the correction of minor deviations in these dimensions. When the deviations are more severe more direct measures may be desirable. When losses of water in excess of solute have resulted in marked increases in concentrations 5 per cent glucose solution will serve as a source of water since the glucose is rapidly metabolized. In some patients a marked decrease of body fluid concentration may be encountered most often because losses of isotonic fluid have been inappropriately replaced with water or 5 per cent glucose. In such instances there may be a place for hypertonic (2 per cent or 3 per cent) sodium chloride solutions since the hypertonic fluids are considerably more efficient in restoring concentrations than is isotonic saline. However a low osmotic pressure (plasma sodium concentration) is often found in association with increased extracellular volume in cardiac failure, cirrhosis and advanced renal failure and the use of hypertonic saline solutions in these conditions is more detrimental than helpful. The pathogenesis and treatment of these abnormalities are discussed more fully in the section on Hyponatremia.

In dehydration with severe acidosis restoration of acid base balance may be hastened if isotonic (one sixth molar) sodium lactate solution is used in place of sodium chloride since oxidation of the lactate makes the sodium available as bicarbonate without interposition of renal activity. Alkalosis is sometimes treated by the intravenous administration of ammonium chloride but the practice is to be discouraged as dangerous and rarely necessary. Ammonium ion absorbed from the gastrointestinal tract is fixed as urea in the liver but administered intravenously it is distributed in the general circulation and may have marked toxic effects on the central nervous system. The possibility that potassium depletion may in part be responsible for alkalosis should be kept in mind.

The addition of potassium chloride to solutions for intravenous use has become common practice for the treatment of potassium depletion. This may under selected circumstances e.g. diabetic acidosis metabolic alkalosis be highly beneficial but

the dangers should be recognized and promiscuous use discouraged. For further details see the section on Hypokalemia.

Certain precautions to be taken in the intravenous administration of saline solutions are especially important in the treatment of patients who have or who are likely to develop cardiac insufficiency. The too rapid administration of fluids in such patients may precipitate pulmonary edema. Keeping infusion rates low, periodic examination of the lung bases for rales, and frequent determination of the venous pressure may minimize the danger. In such persons there may be occasion for subcutaneous administration of saline, but poor absorption may be anticipated in the presence of peripheral circulatory failure. Another occasion for caution is in the treatment of patients with renal insufficiency in which renal function cannot compensate for miscalculation of fluid requirements. This is particularly the case when renal shutdown is complete, even though this may have resulted from dehydration and shock. If when blood pressure has been restored and the peripheral circulation is adequate, a flow of urine has not been established, the further administration of fluids will not "force open" the kidneys, and indeed attempts to do so may be fatal. Conservative expectant treatment with fluid and electrolyte intake carefully balanced to output is required.

Specific consideration of the management of dehydration and disturbances in fluid balance is discussed under diseases in which these problems are of major importance, e.g., diabetes mellitus, adrenal insufficiency, uremia, etc. For normal values of blood constituents, see tables at the end of this book.

### Hyponatremia

**Interpretation.** The finding of a plasma sodium concentration below the normal range is, with a single exception to be mentioned, an indication of a reduced effective osmotic pressure of the body fluids. It is thus a clear indication of dilution of the

body fluids of an excess of water relative to the amount of solute. Since such dilution of the body fluids is normally the stimulus for the excretion of the excess water in a dilute urine, hyponatremia is always a sign of inadequate water excretion. The plasma sodium concentration alone gives no information relevant to the question of whether the body has an excess or a deficit of sodium. The latter can be estimated only from the volume of and concentration of sodium in the extracellular fluid, and since volume changes are likely to be relatively larger than the changes in sodium concentration, extracellular fluid volume is the dominant factor in determining the body sodium content.

(The exception to the equivalence of hyponatremia and low effective osmotic pressure is the relatively unusual situation in which a very high concentration of some solute such as glucose, which does not readily penetrate cells, is present in the extracellular fluid. By drawing water from cells or by keeping administered water in an extracellular position, such solute may dilute the plasma sodium while total effective osmotic pressure is normal or even high.)

**Physiology.** Since impaired water excretion underlies hyponatremia, we may approach its causes by a brief review of those factors which contribute to normal water excretion. The excretion of dilute urine implies separation of solute and water. In the kidney this is accomplished in the distal portions of the renal tubule by the removal of sodium salts from the previously isotonic fluid, leaving the excess of water behind to be excreted in the urine. Three conditions must therefore be met in order that a dilute urine be excreted: (1) An adequate volume of fluid must reach the segment of the tubule in which the dilution occurs; (2) this segment must retain the capacity to reabsorb sodium salts; and (3) the segment in which the dilution occurs and those distal to it must maintain a low permeability to water so that the excess water can not diffuse out of the tubule in response to the osmotic gradient which has been created. In order that these conditions be met: (1) the rate of glomerular filtration must be maintained and an appreciable proportion of the sodium escape reabsorption in the proximal tubule in which no dilution occurs; (2) the sodium reabsorption mechanism must perform adequately; (3) pituitary antidiuretic hormone must be absent, since the specific effect of this hormone is to increase the permeability of the distal portions of the renal tubule to water.

Although the subject has not been fully explored it is probable that any or all of these factors may at times contribute to failure of normal water excretion and hyponatremia

**Pathogenesis and Treatment** In considering some of the more common conditions in which hyponatremia is encountered it is convenient to divide them into those in which hyponatremia is associated with a diminished volume of extracellular fluid and those in which the extracellular volume is expanded

**Hyponatremia with Decreased Extracellular Fluid Volume** The occurrence of hyponatremia with diminished extracellular fluid volume is almost always the result of losses of body fluids with high electrolyte concentrations and their replacement with electrolyte free solutions. This may occur in any situation in which dehydration is encountered—profuse sweating losses of gastrointestinal contents by vomiting or diarrhea fistulous drainage etc. The dilution may occur because the patient replaces these losses of fluid by drinking water or often in hospital practice because the losses are replaced with electrolyte free fluid in the form of 5 per cent glucose solution. In adrenal insufficiency and in renal insufficiency with inability to reduce salt excretion to low levels the electrolyte loss is in the urine. In all of these circumstances the primary event is loss of sodium from the body. This is responsible for the reduction of extracellular fluid volume. The low sodium concentration however is the result of failure of water excretion which in turn is due to various combinations of reduced glomerular filtration changes in sodium reabsorption and not infrequently the secretion of antidiuretic hormone in response to stimuli other than the normal one of increased effective osmotic pressure of the body fluids.

It is important to recognize that a low plasma sodium concentration indicates a low effective osmotic pressure not only of the extracellular fluid but of the intracellular fluid as well since these osmotic pressures are the same. Furthermore since the electrolyte losses which have produced decreased extracellular volumes are generally derived largely from the extracellular compartment the diminished intracellular osmotic pressure is usually the result of the movement of water into cells. Thus the intracellular fluid volume is high and the cells expanded in the presence of the shrunken extracellular fluid. This underlies the chief danger of hyponatremia—the

occurrence of water intoxication. Aside from the possibility or frank presence of water intoxication hyponatremia is to be considered a sign of inadequate handling of fluid and electrolyte balance and not a disorder requiring treatment in its own right.

Treatment should be aimed at the restoration of a normal total sodium content in the extracellular fluid. Under most conditions adequate water excretion is restored when the volume of extracellular fluid is returned to normal so that isotonic chloride solutions can be used for replacement (see section on Dehydration). However more rapid restoration of tonicity and volume can be achieved if part of the solution administered is in the form of hypertonic (2 or 3 per cent) sodium chloride. This is particularly indicated when there is evidence of water intoxication.

**Hyponatremia with Increased Extracellular Fluid Volume** Impairment of water excretion occurs commonly in situations in which there is also a reduction of the excretion of sodium salts. The stage is thus set for a reduction of the osmotic pressure of body fluids—and the plasma sodium concentration—at the same time that the volume and total sodium content of the extracellular fluid is expanded. The extent to which simple dilution or various combinations of dilution and expansion of extracellular fluid may ensue depends on the relative intakes of salt and water.

In most *postoperative* patients the tendency to retain both salt and water is present. The administration of excesses of isotonic saline solution may lead to edema. However because of the recognized danger of producing edema (particularly in those who have undergone cardiac surgery) the administration of salt is often kept low while with an overestimation of the fluid needs of such patients large volumes of 5 per cent glucose are given. Hyponatremia is the predictable result of such overtreatment. This particular type of hyponatremia is easily avoided if its pathogenesis is understood. When it has been inadvertently produced it is generally best treated by a reduction of fluid intake to the lowest feasible level so that insensible water loss and the minimal urinary losses of water can effect a return of the osmotic pressure of body fluids to normal. If there is evidence of water intoxication the administration of hypertonic solutions may be required.

Hyponatremia is commonly encountered in *edematous patients* with cardiac decompensation cirrhosis with ascites or the ne

phrotic syndrome. Such patients have been erroneously considered to be salt depleted and the designation 'low salt syndrome' has been misleadingly applied. While it is true that those patients who develop hyponatremia have usually been subjected to restricted salt intakes and have frequently been given diuretics, the cardiac patients most likely to develop dilution of the body fluids are generally almost unresponsive to diuretics. In fact, the hyponatremia often tends to disappear when responsiveness to diuretics is reestablished. Undoubtedly the universal practice of relying in the treatment of edematous patients upon restriction of sodium intake while allowing a free intake of fluid contributes to the frequency of hyponatremia with edema. The long held belief that a large fluid intake is beneficial to any sick person is also a contributory factor. Whereas the person with a normal sensorium and the capacity to express his needs can be expected to satisfy his thirst when dehydrated, he can not be relied upon to abstain from drinking fluids when he becomes diluted. Fluid intake is largely a matter of habit.

When hyponatremia develops in an edematous person, restriction of water intake to the lowest level compatible with the comfort of the patient is indicated. (In fact, it might well be considered whether some restriction of water intake should not be imposed upon all patients subjected to limited salt intake for the prevention or treatment of edema, even though this would include many able to maintain water balance on an unrestricted intake.) The major therapeutic efforts should be directed against the underlying disease. *Hypertonic salt solution should not be administered* because it increases the edema and further complicates the problem of therapy.

*Hypernatremia* is without exception indicative of an increased effective osmotic pressure of the body fluids and is due to failure of water intake to keep up with losses. It occurs almost exclusively in those who, because of clouded sensorium or inability to communicate, are unable to obtain sufficient water. Diabetes insipidus with excessive losses of water in the urine may be a contributing factor, particularly in those who have suffered head injuries—a group in whom hypernatremia is most frequently encountered. Treatment should be aimed at an adequate water intake by mouth if possible and intravenously as 5 per cent glucose solution if necessary. If the hypertonicity of the plasma is accompanied by a dilute urine, diabetes insipidus

is almost certainly present and should be treated by the administration of pituitary antidiuretic hormone. If an aqueous solution is administered, it must be given at frequent and regular intervals (0.5 to 1.0 units of vasopressin every three hours). Solutions of vasopressin tannate in oil can be used to maintain continuous antidiuresis (2 to 5 units every two to three days). When vasopressin is used particularly the long acting preparations, caution must be used to avoid the administration of excessive amounts of water. The amounts given should be just sufficient to reduce the plasma sodium concentration to normal and to maintain it at that level.

## Hypokalemia

**Interpretation.** The plasma potassium concentration requires consideration in two respects: first, because the level of potassium in the extracellular fluid has a direct effect on certain functions, especially muscular (including cardiac) and neuromuscular; and second, because taking into consideration certain factors which influence the distribution of potassium within the body, the plasma potassium concentration can be a useful index of the presence of deficits or excesses of body potassium.

Since only a small part of the body potassium is contained in the extracellular fluid, marked changes in the potassium concentration of this compartment can occur with shifts into and out of cells involving relatively small changes in the potassium content of the cells. Potassium tends to move into cells with cell growth and nitrogen deposition and to move out as cells are destroyed or in those situations usually associated with negative nitrogen balance. Potassium moves into cells when glycogen is deposited and out of cells when it is broken down. The equilibrium between extracellular and intracellular potassium is shifted toward the cells in alkalosis so that the plasma potassium falls as extracellular pH rises; conversely, in acidosis the plasma rises as a result of the shift of potassium out of cells. On the other hand, the plasma potassium is not greatly affected by changes in the volume of extracellular fluid while the plasma potassium may be temporarily diluted by rapid expansion of the extracellular fluid volume. The tendency to maintain a constant ratio of intracellular to extracellular concentration rapidly restores the plasma potassium concentra-

Although the subject has not been fully explored it is probable that any or all of these factors may at times contribute to failure of normal water excretion and hyponatremia

**Pathogenesis and Treatment** In considering some of the more common conditions in which hyponatremia is encountered it is convenient to divide them into those in which hyponatremia is associated with a diminished volume of extracellular fluid and those in which the extracellular volume is expanded

**Hyponatremia with Decreased Extracellular Fluid Volume** The occurrence of hyponatremia with diminished extracellular fluid volume is almost always the result of losses of body fluids with high electrolyte concentrations and their replacement with electrolyte free solutions. This may occur in any situation in which dehydration is encountered—profuse sweating losses of gastrointestinal contents by vomiting or diarrhea fistulous drainage etc. The dilution may occur because the patient replaces these losses of fluid by drinking water or often in hospital practice because the losses are replaced with electrolyte free fluid in the form of 5 per cent glucose solution. In adrenal insufficiency and in renal insufficiency with inability to reduce salt excretion to low levels the electrolyte loss is in the urine. In all of these circumstances the primary event is loss of sodium from the body. This is responsible for the reduction of extracellular fluid volume. The low sodium concentration however is the result of failure of water excretion which in turn is due to various combinations of reduced glomerular filtration changes in sodium reabsorption and not infrequently the secretion of antidiuretic hormone in response to stimuli other than the normal one of increased effective osmotic pressure of the body fluids

It is important to recognize that a low plasma sodium concentration indicates a low effective osmotic pressure not only of the extracellular fluid but of the intracellular fluid as well since these osmotic pressures are the same. Furthermore since the electrolyte losses which have produced decreased extracellular volumes are generally derived largely from the extracellular compartment the diminished intracellular osmotic pressure is usually the result of the movement of water into cells. Thus the intracellular fluid volume is high and the cells expanded in the presence of the shrunken extracellular fluid. This underlies the chief danger of hyponatremia—the

occurrence of water intoxication. Aside from the possibility or frank presence of water intoxication hyponatremia is to be considered a sign of inadequate handling of fluid and electrolyte balance and not a disorder requiring treatment in its own right.

Treatment should be aimed at the restoration of a normal total sodium content in the extracellular fluid. Under most conditions adequate water excretion is restored when the volume of extracellular fluid is returned to normal so that isotonic chloride solutions can be used for replacement (see section on Dehydration). However more rapid restoration of tonicity and volume can be achieved if part of the solution administered is in the form of hypertonic (2 or 3 per cent) sodium chloride. This is particularly indicated when there is evidence of water intoxication.

**Hyponatremia with Increased Extracellular Fluid Volume** Impairment of water excretion occurs commonly in situations in which there is also a reduction of the excretion of sodium salts. The stage is thus set for a reduction of the osmotic pressure of body fluids—and the plasma sodium concentration—at the same time that the volume and total sodium content of the extracellular fluid is expanded. The extent to which simple dilution or various combinations of dilution and expansion of extracellular fluid may ensue depends on the relative intakes of salt and water.

In most postoperative patients the tendency to retain both salt and water is present. The administration of excesses of isotonic saline solution may lead to edema. However because of the recognized danger of producing edema (particularly in those who have undergone cardiac surgery) the administration of salt is often kept low while with an overestimation of the fluid needs of such patients large volumes of 5 per cent glucose are given. Hyponatremia is the predictable result of such overtreatment. This particular type of hyponatremia is easily avoided if its pathogenesis is understood. When it has been inadvertently produced it is generally best treated by a reduction of fluid intake to the lowest feasible level so that insensible water loss and the minimal urinary losses of water can effect a return of the osmotic pressure of body fluids to normal. If there is evidence of water intoxication the administration of hypertonic solutions may be required.

Hyponatremia is commonly encountered in edematous patients with cardiac decompensation cirrhosis with ascites or the ne

tubule for exchange with potassium. On the other hand, although aldosterone secretion may be as great in patients with severe cardiac failure or cirrhosis as in those with aldosterone-secreting tumors, the cardiac or cirrhotic patient develops little or no potassium depletion because the relatively complete retention of salt leaves little sodium for exchange with potassium. However, when urinary electrolyte excretion is forced by the administration of diuretics, large and rapid losses of potassium may be produced.

Potassium depletion is thus most likely to be encountered in situations in which excessive adrenal steroids are present—as a result of the presence of hormone-secreting tumors or following the administration of exogenous steroids under conditions of stress and trauma as in postoperative patients and in diabetic acidosis following the response to diuretics in edematous patients with salt-losing kidney lesions as in renal tubular acidosis when there are large losses of gastrointestinal fluids (particularly if renal losses are accelerated by administration of more saline solution than absolutely required) and when large amounts of ion-exchange resin are administered to salt-retaining patients.

**Prevention and Treatment.** In many instances potassium depletion can be prevented by recognition of circumstances likely to lead to its occurrence. In patients given adrenal steroids, potassium depletion can be largely avoided by sharp restriction of sodium intake and, if necessary, by supplementation of the normal dietary potassium intake with 5 to 10 gm of potassium chloride per day. In patients losing large volumes of gastrointestinal fluids, the development of potassium deficits should be anticipated if the losses are continued beyond a few days; if the parenteral route is the only possible means of administration, potassium chloride should be added at a concentration not in excess of 50 mEq per liter to be administered at a rate not exceeding 15 mEq per hour. The parenteral administration of potassium is hazardous because of the cardiac effects of a high plasma potassium, and if potassium is administered too rapidly cardiac effects may be precipitated even in the depleted patient. Parenteral administration should be avoided if potassium-containing fluids or better a normal diet possibly supplemented with potassium chloride can be given by mouth. The advantages of restriction of sodium intake in facilitating the replacement of potassium deficit should be recognized.

When potassium is administered parenterally, it is advisable to follow the electrocardiogram for changes characteristic of potassium intoxication and, if possible, to obtain frequent determinations of the plasma potassium concentration. Potassium should not be administered unless there is an adequate level of renal function.

ROBERT W. BERLINER

## Acidosis

**Definition.** Acidosis is an abnormal condition caused by the accumulation in the extracellular fluids of excess acid (hydrogen ions) or by the loss from the body of alkali (substances like bicarbonate which bind hydrogen ions). The more common cause is the accumulation of acid, that is, a state in which acids are formed or absorbed more rapidly than they can be destroyed or eliminated. This process may be considered to have produced a state of acidosis when it has caused either the bicarbonate of the blood to fall or the hydrogen ion concentration to rise above the normal limits.

**Etiology.** Acidosis is a symptom complex, not a disease in itself. Acidosis of clinical importance is observed chiefly in diabetes,\* renal disease, certain diarrheas, cyclic vomiting in children, and poisoning by salicylates or methanol.

Severe acidosis may complicate implantation of the ureters into the sigmoid colon. It may also occur in pulmonary emphysema, bronchitis, or extensive fibrosis from impaired pulmonary exchange of gases.

**Physiology and Chemistry.** The body fluids are mildly alkaline, and even in the most extreme acidosis compatible with life they remain on the alkaline side of neutrality; i.e., in acidosis the body becomes more weakly alkaline than normal. Reaction (degree of acidity or alkalinity) of fluids is customarily noted in terms of pH, which is the negative logarithm of the H<sup>+</sup> ion concentration. The H<sup>+</sup> ion concentration of blood is something less than one ten-millionth normal. It may be described as having a hydrogen ion concentration of  $10^{-7.4}$  or more conveniently as having a pH of 7.4. In adopting this logarithmic form of expression, however, it must be realized that a fall in pH from 7.4 to 7.2

\* Diabetic acidosis is discussed in detail in the section on Diabetes.

tion to very nearly the level existing before the expansion

In interpreting the significance of a particular concentration of potassium in the plasma and whether or not the administration of potassium is likely to be indicated some consideration must be given to these factors affecting the distribution of potassium within the body. For instance the patient in diabetic acidosis may be found to have a high plasma potassium but taking into account the fact that restoration of the blood pH to normal and reconstitution of depleted glycogen stores will both cause a shift of potassium into cells it may be seen that the plasma potassium is certain to fall even if there are no further external losses and that this fall may well carry below the normal range.

**Effects of Hypokalemia** It is sometimes difficult to distinguish the results of reduced extracellular potassium concentration itself from those due to potassium depletion since the two are so often associated. The most striking symptom of hypokalemia muscular weakness which may progress to paralysis of the extremities and eventually to impairment of respiratory movements is clearly associated with the depressed extracellular potassium concentration and although it may be associated with potassium depletion it can occur without external potassium losses as in periodic paralysis. The electrocardiographic changes associated with hypokalemia prolongation of the Q-T interval depression of the S-T segments and flattening of the T waves are also the result of the reduced extracellular potassium. A reduced plasma potassium concentration also potentiates the effects of digitalis glycosides and in the digitalized patient digitalis toxicity may be precipitated by potassium losses leading to hypokalemia. A number of symptoms and signs associated with hypokalemia combined with potassium depletion are probably dependent largely on the latter or on both apathy distention or even paralytic ileus alkalosis and depression of renal function. Necrosis and hyalinization of cardiac and skeletal muscle fibers and vacuolar lesions in the renal tubules are observed with more severe grades of potassium depletion.

The plasma potassium concentrations at which various effects are observed vary widely in different persons and from time to time. The reasons for this are not entirely clear. It is sometimes stated that it is the ratio of extracellular to intracellular potassium concentration which is the im-

portant variable. This ratio is under most conditions very difficult to determine. However it should be noted that the concentration changes in extracellular fluid are virtually always greater than those in intracellular fluid so that a reduced plasma potassium almost always means a low extracellular to intracellular concentration ratio and an elevated plasma potassium the reverse.

**Pathogenesis** Factors which may produce a lowered plasma potassium by internal redistribution have already been discussed. In most instances significant hypokalemia is the result of external losses of potassium through losses of gastrointestinal fluids urinary excretion or both. Potassium is present in all the gastrointestinal secretions at concentrations higher than in extracellular fluid so that continued loss of such secretions may account for considerable potassium deficits. These gastrointestinal losses are likely to be the more significant because they are often associated with complete interruption of potassium intake and because they are often accompanied by continuing losses of potassium in the urine for reasons to be discussed.

Although the kidney is capable of decreasing potassium excretion to very low levels when under no stress other than reduced potassium intake with mild consequent potassium deficit potassium excretion under other stresses often remains at an inappropriately high level because of the necessity to excrete some electrolyte under conditions where there are strong stimuli to retain sodium. This usually involves the effect of adrenocortical steroids on renal electrolyte transport with substitution of potassium for sodium in the urine.

The renal effect of adrenal steroids pertinent to the production of potassium losses is upon the exchange of potassium and sodium ions. In order that potassium ions be secreted into the urine it is necessary that sodium ions be delivered to the site presumably in the distal tubule at which this exchange is effected. Consequently potassium losses are relatively great when electrolyte output is large and may be small or absent if salt intake (and consequently chloride excretion) is markedly restricted or if because of accumulation of most of the sodium intake in the form of edema the output of electrolyte in the urine is low. Thus potassium depletion is marked in primary aldosteronism because sodium intake continues and net sodium retention is virtually negligible. Thus plenty of sodium is available at all levels in the renal

neys with apparently normal glomerular function may lack the normal tubular function of acidification with resulting acidosis. The inability to acidify the urine together with the increased urinary excretion of calcium in acidosis may produce osteoporosis and nephrocalcinosis. Other renal tubular functions such as production of ammonia and reabsorption of glucose, phosphorus, potassium and amino acids may also be defective in such patients.

*Starvation acidosis* is of especial importance since it plays an important role as a complicating factor in disease. It is due to unavailability of preformed carbohydrates and can be produced as well by severe restriction of carbohydrate intake as by complete starvation. The reduction of bicarbonate is due to displacement by abnormal amounts of ketone acids. The increased ketone production is related to increased utilization of fat as it is in diabetes.

The acidosis of *cyclic vomiting* of children is largely if not entirely the result of starvation ketosis to which children are particularly susceptible.

*Loss of alkaline intestinal fluids* in considerable volumes may lead to acidosis. This seldom reaches important proportions except in Asiatic cholera in which large amounts of liquid alkaline fluid may be passed and in some of the diarrheas of infancy. Losses of biliary or pancreatic secretions by fistulas or surgical drainage may likewise produce acidosis. Starvation by increasing ketone production and dehydration by impairing the base sparing functions of the kidneys enhance the acidosis.

The *ingestion of ammonium chloride* produces acidosis because the ammonia is quantitatively converted to urea in the liver leaving chloride ion to displace bicarbonate from the plasma. Ingested calcium chloride produces a similar effect because calcium is largely excreted by the gut in combination with phosphate, carbonate and soaps while the chloride remains to encroach upon plasma bicarbonate. Both ultimately affect plasma bicarbonate just as hydrochloric acid would.

*Acetazolamide* a diuretic drug which inhibits carbonic anhydrase causes acidosis by slowing the rate at which hydrogen ion can be secreted by the renal tubules thereby reducing the excretion of ammonium ion and titratable acid and increasing greatly urinary losses of bicarbonate.

Severe hyperchloremic acidosis may occur as a complication of ureterosigmoid anastomoses. This is due largely to absorption of ammonium salts from the bowel.

*Pulmonary or circulatory diseases* which interfere with the exchange of gases between blood and alveolar air may produce acidosis by allowing an abnormal accumulation of carbon dioxide in the body. There is a compensatory increase in serum bicarbonate which tempers the decrease in pH. The increase in serum bicarbonate is effected by augmented tubular reabsorption of bicarbonate in response to elevated carbon dioxide tension.

The respiratory centers demonstrate diminished sensitivity to change in pH or pCO<sub>2</sub> during prolonged hypercapnia. Under these circumstances decreased oxygen tensions may displace acidosis as the dominant determinant of respiratory ventilation. Exposure to high concentration of oxygen by diminishing anoxia may provoke intolerable acidosis.

Acidosis commonly complicates diseases which quite apart from acidosis are characterized by severe dehydration. Thus in diarrheas and cyclic vomiting loss of intestinal contents leads to severe dehydration in itself. In nephritis and diabetes polyuria, vomiting and excessive loss of water through pulmonary ventilation all contribute to dehydration. The fluids of the body become so depleted that blood volume may fall below the point at which the circulation can be supported.

The larger part of the base lost is sodium. This comes almost entirely from the extracellular fluids which also yield variable amounts of water so that the concentration of sodium in plasma and extracellular fluids may be reduced normal or even occasionally elevated. Variable amounts of the normal small intracellular component of sodium leave the cells during acidosis and contribute to the overall sodium loss.

Considerable amounts of potassium the major intracellular base are also lost during acidosis. The effect on plasma potassium will depend to a large extent on the intake of potassium; the severity of dehydration and the functional status of the kidneys. Thus in advanced renal disease with obligatory polyuria treated with fluids lacking in potassium the concentration of potassium may be subnormal in plasma as well as in cells. This is true also in primary renal tubular dysfunction in which reabsorption of potassium as well as secretion of acid may be impaired. In most instances of acidosis however accompanied as they are by oliguria the discharge of potassium from cells results in elevated plasma potassium. This is especially pronounced if excessive protein breakdown and glycogen

represents a doubling of H ion concentration. The extremes of pH encountered in disease are something of the order of 7.0 and 7.7.

Normal body function depends on maintenance of the reaction of body fluids within relatively narrow limits between pH 7.35 and 7.45. This regulation is dependent on the buffer properties of blood and other body fluids, regulation of carbon dioxide excretion by the lungs and renal function.

**Buffer Effect.** Substances which by their presence in solution decrease the pH change caused by the addition of acid and alkali are called buffers. They are mixtures of a weak acid and its alkali salt or of a weak base and its acid salt. The buffers of physiological importance are mixtures of weakly dissociated acids and their strongly dissociated salts. Those of significance are carbonic acid and  $\text{HCO}_3^-$ ,  $\text{HPO}_4$  and  $\text{H}_2\text{PO}_4$ , proteins (including hemoglobin and tissue protein) with base proteinate and organic phosphates with their basic salts. Together these comprise approximately one third of the alkali normally present in plasma and probably a greater fraction of the alkali of the cells of the body.

**Respiratory Regulation.** In any mixture of a weak acid and its salt the pH of the solution is determined by (and in turn determines) the ratio of free acid to salt in the mixture. The reaction of blood therefore depends on the ratio of free carbonic acid to bicarbonate  $\frac{\text{HCO}_3^-}{\text{HCO}_2}$  which

at normal pH of 7.35 is about 1:20. The concentration of carbonic acid in this equation is directly related to the carbon dioxide tension in the blood. Since carbon dioxide which is constantly formed in abundance in cellular oxidations is excreted through the lungs, the carbon dioxide tension may be altered rapidly by change in respiration. Other factors being constant, the carbon dioxide tension of the blood decreases with deep respiration and increases with shallow respiration. The carbonic acid bicarbonate buffer is thus much more effective *in vivo* than *in vitro* since in the latter the addition of strong acid causes a comparable increase in carbonic acid while in the former carbonic acid becomes decreased below its original level through increased pulmonary ventilation. The appropriate change in ventilation is determined by the medullary respiratory center in response to pH and pCO.

\* B = base (sodium or potassium)

**Renal Regulation.** The metabolism of the ordinary diet yields phosphoric and sulfuric acid equivalent to 400 to 800 ml or more of tenth normal acid. If this were excreted as neutral sodium salts the body would rapidly be depleted of cation. This is normally excreted by the following mechanisms. First, the renal tubules synthesize ammonia which combines with secreted hydrogen ion to convert the sodium salts of glomerular filtrate into ammonium salts, thereby removing hydrogen ion from the body. Second, the renal tubules convert the slightly alkaline glomerular filtrate into acid urine which permits the excretion of weak acids such as uric, citric and beta-hydroxybutyric in the free form. The cells of the distal tubules derive the hydrogen ions for this purpose from carbonic acid which they can form rapidly from carbon dioxide by the action of carbonic anhydrase. The most acid urine which the kidney can elaborate has a pH of 4.5 at which reaction no significant amounts of strong acids such as sulfuric or hydrochloric can exist in free form. Hence base can be spared in the excretion of these acids only by substitution of ammonia. Finally, the secretion of hydrogen ions in exchange for sodium by the renal tubules permits the complete absorption of bicarbonate from glomerular filtrate, thus insuring against the loss of cation (bicarbonate) in the urine.

**Pathological Physiology and Chemistry.** The abnormally high H ion concentration of acidosis is almost always the result of decrease in the denominator of the carbonic acid bicarbonate ratio. This decrease in bicarbonate is, however, never a primary event. It is always caused by the accumulation in the body of an excess of acid other than carbonic or by the loss from the body of alkali, more commonly the former.

In the acidosis of advanced renal disease bicarbonate is reduced chiefly by accumulation of abnormal amounts of phosphoric, sulfuric and organic acids. Poor food intake and vomiting may increase ketone production. A further factor encroaching upon bicarbonate is diminution of the sodium of plasma by failure of the renal mechanisms for conservation of base in excreting acids. The ability of the damaged kidney to acidify the urine and to form ammonia is much impaired. The base conserved by these mechanisms in the acidosis of advanced nephritis is a small fraction of that saved by these mechanisms in diabetic acidosis of comparable degree. Kid

stium deficit Physiological saline solution is of prime importance to replace losses of water and electrolytes by parenteral routes Approximately 100 ml per kilogram of body weight is necessary to correct severe dehydration Half of this should be given within the first hour or two if possible and the remainder in the course of the next few hours Sufficient glucose (or fructose or invert sugar) must be supplied to reduce protein breakdown and excessive ketone formation For this purpose at least 2 gm per kg of body weight should be given daily and it is probably advisable to give twice this much This may be given as 5 or 10 per cent solution intravenously until oral feeding becomes possible The glucose should be given in distilled water unless the plasma sodium is subnormal in which case it may be given in physiological saline solution

Alkali may be used to speed relief of hyperpnea in the acidosis associated with diarrhea especially in infants in whom the renal regulatory mechanism is incompletely developed Alkali may be given as bicarbonate (2 to 3 per cent) or lactate (one sixth to one half molar) intravenously In the body lactate is converted to glycogen leaving sodium available for neutralization of acid Patients with acidosis severe enough to provoke recognizable hyperpnea may be given 7 ml of 4 per cent bicarbonate (or 25 ml of one sixth molar lactate) per kg of body weight with impunity It is rarely necessary to give more to relieve the hyperpnea and it matters little if plasma bicarbonate is not restored to normal levels immediately Various preparations containing sodium potassium bicarbonate (or lactate) and chloride in proportion to those found in normal intestinal fluids are available commercially These may be substituted freely if desired for physiological saline in replacing current losses of intestinal fluids

Massive infusions of physiological saline solution may be given subcutaneously with impunity If the circulation is adequate this is absorbed with extreme rapidity by the severely dehydrated patients as much as 3 liters being commonly absorbed within two hours Failure of the severely dehydrated patient to absorb subcutaneous fluid rapidly denotes circulatory collapse and is an indication for prompt blood transfusion or administration of plasma Glucose solutions should not be given subcutaneously since they cause a temporary net loss of available salt to the tissue because salt diffuses into them more rapidly than glu-

cose diffuses out All these considerations unimportant as they may seem in most cases may be important in individual cases in tipping the balance into circulatory collapse which is a prime threat to life If any evidence of shock is present blood plasma or plasma substitute should be given without delay

The parenteral administration of potassium serves to minimize the risk of serious depression of plasma potassium during treatment with parenteral fluids and glucose and also speeds the restoration of normal cellular potassium The potassium should not be given at the start of treatment when plasma potassium is commonly normal or elevated lest plasma potassium rise to the point at which fatal heart block ensues (approximately 10 mm per liter) Ideally it should be given only after a sharp depression of plasma potassium has been demonstrated by analysis In the absence of facilities for such analyses evidence of subnormal potassium levels may be detected by electrocardiographic changes These are in order of their appearance prolonged QT interval low T waves sagging ST segments and depressed ST take-off the last occurring at levels of 15 mm or less In any event potassium should not be given until sufficient saline and if necessary blood or plasma is given to insure adequate circulatory status and urine flow If neither chemical determinations nor electrocardiograms are available it is probably safe to give potassium six to eight hours after the start of therapy unless shock or anuria is present For general use it is probably safest to use considerably less than the maximal amount of potassium tolerated It is suggested that 0.1 to 0.15 gm of potassium chloride per kg be given intravenously over a period of not less than four hours When feeding is resumed there is no clear indication for supplementary potassium since most foods contain it in abundance although in the opinion of some complete recovery is speeded by the addition of potassium salts to the diet If feeding can be resumed within six to eight hours of the start of treatment it is probably desirable to dispense with the parenteral administration of potassium since both fruit juices and milk as well as most other foods contain considerable potassium and supplementary potassium chloride can be given by mouth if desired The risk however slight of producing fatal elevation of plasma potassium by parenteral administration is thus avoided

depletion add to the release of potassium from cells or if circulatory collapse is present. During treatment with large amounts of fluid and glucose however plasma potassium falls sharply as a result of continued urinary loss, dilution by expansion of extracellular fluid volume and transfer into cells during resumption of carbohydrate utilization. In infantile diarrhea or diabetic acidosis for example serum potassium frequently falls below 2 millimols per liter during intensive treatment with parenteral glucose, water and salts other than potassium. Muscular paralysis, cardiac abnormalities and even death have been attributed to this fall in plasma potassium. Acidosis decreases neuromuscular excitability. There is some evidence that it impairs utilization of carbohydrate. Chronic acidosis may produce severe decalcification of bones with pathological fractures. It presumably affects many other functions to varying degrees.

Calcium is also wasted in acute acidosis, plasma levels being maintained by transfers from bone. In some circumstances during treatment of infantile diarrhea with parenteral fluids, serum calcium may fall to a degree which produces tetany and possibly other serious derangements.

**Symptoms.** Mild acidosis has no recognizable symptomatology. Hyperpnea, tachycardia, drowsiness, nausea, stupor and coma are characteristic of severe acidosis. Of these only hyperpnea is unequivocally related to the acidosis *per se*. Respiration is extremely deep and the rate is increased. Overventilation usually becomes apparent when the bicarbonate falls to 30 volumes per 100 ml, but does not become severe until it falls below 20 volumes per 100 ml. In the terminal state respiration becomes weak and irregular. Whether or not the cerebral symptoms can be related to acidosis has not been established. It seems probable that circulatory changes secondary to the severe dehydration which regularly accompanies acidosis play an important role. In support of this hypothesis is the similar mental picture observed in the shock or impending shock of severe dehydration in diseases in which acidosis is not present, also in the observation that drowsiness may often be alleviated by transfusion or fluid administration before there has been any relief of acidosis. It seems probable that accumulation of ketone bodies plays a part in the production of the cerebral changes in diabetic acidosis.

**Diagnosis.** Mild acidosis cannot be recognized clinically but may be diagnosed by

determination of serum or plasma bicarbonate. Values between 30 and 55 volumes per 100 ml indicate mild acidosis. Severe acidosis is recognized by the extraordinary air hunger. The breathing is deep and rapid. The diagnosis may be confirmed by determination of the carbon dioxide content, combining power or the pH of plasma. Hyperpnea, dehydration and drowsiness even without any available history should suggest diabetes which may be confirmed by the presence of sugar and acetone in the urine.

Detection of acidosis in patients with abnormal loss of alkaline intestinal secretions or with ureterosigmoid anastomoses depends on suspicion of the possibility. In renal disease severe acidosis is manifest by hyperventilation but moderate acidosis of long duration may be asymptomatic. Awareness of this possibility in patients with dwarfism or with unexplained decalcification of the bones may lead to the primary diagnosis of chronic renal disease, especially the type with renal tubular dysfunction in which the urine may be free of albumin.

**Prognosis.** Death probably never results from acidosis *per se*. The prognosis depends first upon that of the underlying or complicating disease and second upon the state of the circulation. The outlook of the patient with the acidosis of advanced renal insufficiency is understandably poor. Recognition of asymptomatic acidosis in renal disease may improve prognosis in respect to decalcification of bones and may initiate therapy to accelerate growth if retarded. The outcome of acute diarrhea or cyclic vomiting is dependent less on the degree of acidosis than on the extent to which the circulation has been compromised by loss of water and salt and on the degree to which depletion of potassium has progressed. Sudden deaths during apparently successful therapy of infantile diarrhea have been ascribed to the development of subnormal levels of potassium in the plasma. Prognosis is improved by the prompt use of blood or plasma in combating circulatory collapse and by supplying potassium at the proper time. A rapidly fatal outcome in the acidosis complicating ureterosigmoidostomy is readily averted by simple measures.

**Treatment.** In acidosis due to excessive loss of alkaline intestinal secretions in diarrheal stools or from fistulas or surgical drainage, correction of the acidosis is usually less urgent than that of dehydration, circulatory collapse, starvation and potas-

ences of alkalosis and hypocalcemia are additive however is demonstrated by amelioration of hypocalcemic tetany by administration of acid or acidifying salts and by the precipitation of tetany in hypercalcemic terminal nephritics by alkali administration.

**In alkalosis the cells contain subnormal amounts of potassium and excessive amounts of sodium.** This disturbance of composition is not necessarily associated with abnormal concentrations of sodium and potassium in the serum.

**Symptoms.** The symptoms of alkalosis are those of the underlying disease plus those of tetany. Tetany is discussed in details elsewhere in this volume.

**Diagnosis.** If the possibility of alkalosis is entertained in patients with vomiting and tetany diagnosis presents no difficulty. The plasma bicarbonate is markedly elevated (to as high as 140 volumes per cent) and plasma chloride proportionately reduced. Serum calcium is within normal limits. In patients receiving alkali for gastric acidity alkalosis should be suspected when vomiting increases or evidence of renal insufficiency develops even in the absence of tetany and confirmation should be sought by determination of plasma bicarbonate. Tetany in the presence of hyperventilation should suggest alkalosis. If this is of brief duration as in sighing or hysterical breathing plasma bicarbonate and serum calcium are both within normal limits. In more prolonged hyperventilation as in disease of the central nervous system plasma calcium is again normal but bicarbonate may be subnormal. Thus we have the paradoxical situation in which hyperventilation and reduction of plasma bicarbonate accompany alkalosis and not acidosis. Determination of pH will of course make the differentiation but this is usually not necessary if the possibility of alkalosis is entertained in such cases and the usual causes of acidosis are excluded.

**Prognosis.** The prognosis is that of the disease which it complicates. Severe tetanic spasms of the larynx or skeletal musculature may contribute to a fatal outcome.

**Treatment.** The alkalosis which results from loss of acid secretions requires treatment no more urgently than does the accompanying dehydration, starvation and potassium depletion. Carbohydrate must be supplied to reduce ketosis and protein

wastage and precautions taken against circulatory collapse as described for acidosis. Approximately 80 ml of fluid per kg of body weight is required to correct severe dehydration. In most instances physiological saline suffices, chloride being selectively retained by the kidneys. If tetany is severe ammonium chloride may be given initially (2 to 500 ml of 2 per cent solution) along with physiological saline intravenously but this is rarely necessary. Sodium chloride in itself can restore extracellular fluid volume but cannot fully correct the alkalosis until replacement of cellular potassium is effected. The latter provokes transfer of hydrogen ions from cells to extracellular fluids and permits the kidneys again to elaborate an alkaline urine thus sparing hydrogen ions for correction of extracellular alkalosis. Potassium is required in large amounts not only to prevent the consequences of hypokalemia (as described under acidosis) but more important to correct fully the large cellular deficit. Retention of more than 500 mEq (38 gm of potassium chloride) may occur during treatment. When urine flow is good there is no risk in giving large amounts of potassium parenterally or orally. It is of course desirable to control treatment by analysis of the serum for potassium and to follow electrocardiograms as described for the treatment of acidosis.

In hyperventilation tetany treatment of the underlying disease is the prime indication. Breathing mixtures of 5 per cent carbon dioxide in oxygen will afford relief of the tetany of primary hyperventilation though this is hardly necessary in the hysterical group.

**Renal Acidosis** - Acidotic hyperpnea should be allayed if possible by administration of alkali. This may be tolerated by mouth but more often must be given intravenously (as 4 per cent bicarbonate or one sixth molar lactate). It is neither necessary nor desirable to restore the plasma bicarbonate to normal. Attempts to do so may precipitate tetany or edema. In the hyperpneic patient 7 ml of 4 per cent bicarbonate or 25 ml of one sixth molar lactate per kg of body weight may be given slowly. This must be repeated if hyperpnea persists or recurs. Smaller doses seldom give any relief. If tetany supervenes administration of alkali must be slowed or stopped if severe especially with laryngospasm. 1 gm of calcium chloride should be injected slowly intravenously (as 10 per cent solution) and repeated if necessary. Asymptomatic reduction of serum bicarbonate may be treated by daily doses of sodium bicarbonate or citrate sufficient to correct the deficit partially (2 to 6 gm daily in divided doses). If heart failure makes the use of sodium salts undesirable the potassium salts may be substituted provided of course serum potassium is not considerably elevated.

The use of alkali is imperative in those cases of primary renal tubular disease in which prolonged though often asymptomatic acidosis contributes to the production of osteoporosis. These patients should also receive supplements of calcium lactate (2 to 4 gm daily) and vitamin D (50 000 units daily). Some patients with renal tubular defect waste potassium sufficiently to cause muscular weakness and electrocardiographic abnormalities. Large supplements of potassium may prove necessary to compensate for this deficiency.

The acidosis of ureterosigmoidostomy is corrected by salt restriction, supplements of sodium bicarbonate or citrate and care to evacuate the rectum frequently.

## Alkalosis

**Definition** Alkalosis is an abnormal condition caused by the accumulation in the extracellular fluids of an excess of alkali or by the loss of acid (hydrogen ions) more commonly the latter. The bicarbonate of the blood is increased (with one exception which is described later) and its hydrogen ion concentration is diminished.

**Etiology** Alkalosis may occur from excess alkali intake. It also follows loss of acid secretions from vomiting or gastric suction. Depletion of body potassium which accompanies the above in itself provokes alkalosis. Presumably the intracellular potassium ions lost are replaced by hydrogen ions from the extracellular fluids. Alkalosis secondary to loss of potassium is seen commonly in patients with biliary and intestinal fistulae, severe diarrhea and in patients maintained for long periods of time on parenteral feedings without added potassium as well as in patients secreting or receiving large amounts of adrenal cortical hormones. Alkalosis may result from loss of carbonic acid through hyperventilation in response to functional or organic disease of the central nervous system or to anoxemia.

**Pathological Physiology and Chemistry** Alkalosis due to excessive loss of acid and potassium in intestinal secretions is always accompanied by severe dehydration. Paradoxically urine is usually acid in this situation since secretion of hydrogen ions by the kidney is promoted by potassium depletion as well as by the intense stimulus of dehydration to the reabsorption of sodium ions. In alkali excess alkalosis change in pH is opposed by increase in carbon dioxide tension of the body fluids through diminished pulmonary ventilation. Conversely the alkalosis of primary overventilation is tempered by decrease in the bicarbonate of the body fluids. Renal tubular reabsorption of bicarbonate has been shown to be regulated by the carbon dioxide tension of the body fluids.

The most striking manifestations of alkalosis are those of neuromuscular hyperexcitability. These are indistinguishable from those of hypocalcemia though there is no clear evidence that they exert their effect indirectly through calcium. That the influ

and frequently will cease to be fat after puberty. True Frohlich's syndrome is exceedingly rare and difficult to diagnose before the normal age of onset of puberty.

Then there comes the child who does not do well in school. There is a feeling among would-be progressive educators that such a situation demands a survey by an endocrinologist. In the author's experience there is only one endocrine abnormality which leads to mental retardation, namely cretinism. The diagnosis of this condition is a problem for the obstetrician and the pediatrician, not for the endocrinologist. If it is not made in the first few weeks or at the most months of life, the damage is already done and one might just as well not make the diagnosis. Parenthetically it might be added that every physician should suspect cretinism in any child with an umbilical hernia at birth which persists after the first few weeks of life. Even juvenile myxedema is not associated with retarded mentality. To be sure, long-standing hypoparathyroidism leads to epileptic seizures and secondary mental retardation. The author has seen in consultation a number of children with poor school records and a date has been unable to make a diagnosis of endocrine disease in any of them. He is impressed by the fact that many of them have been "mirror readers."

Thirdly, the author has yet to see a homosexual patient in whom the trouble was based on faulty endocrine function or in whom the giving of a hormone influenced the direction of the libido. Of interest in this connection is an observation made by Dr. Anne P. Forbes and known in our clinic as "Forbes's law." A patient who complains of impotence or of lack of libido does not suffer from a hormonal lack; a patient with real endocrine insufficiency, e.g., eunuchoidism, has impotence and absent libido but does not complain of them but of something more trivial, such as being mistaken for a girl over the telephone.

A fourth type of case sent to the endocrinologist is the patient with some congenital disorder of the germ plasma, such as mongolian idiocy, Laurence Moon Biedl syndrome, and so on. Just why such conditions should be confused with endocrinopathies is not clear. It is probably connected with the belief that anything which is not fully understood belongs to endocrinology.

Finally, there are the patients with alopecia areata. The endocrines have something to do with certain types of hair; these patients have too little hair, there-

fore they are sent to the endocrinologist. However, the fact that this condition starts by being spotty is strong evidence against an endocrinological etiology. It makes no difference that one spot may enlarge to the points where it covers the whole body; the disease is still a "spotty" one. Endocrinological diseases are generalized, not localized; hormones do not stop in the midline or proceed down one limb and not the other. For example, Paget's disease of bone is not endocrinological since it is not generalized. Though it involves 95 per cent of the skeleton, there will still be a sharp demarcation between the uninvolved part and the Paget's disease. Postmenopausal osteoporosis on the other hand may be confined to the spine and pelvis and still be a generalized disease since here there is a rhyme and a reason to the distribution. This discussion concerns the primary lesion produced by an endocrinopathy. Secondary complications can be spotty (e.g., gangrene of the toe in diabetes, bone cyst with hyperparathyroidism).

**Failure of End Organs to Respond to Hormones.** Since a hormone acts somewhere, it is obvious that one might get much the same clinical syndrome from failure of the end organ to respond to the hormones as one would get with absence of the hormone itself. For example, let us take "pseudohypoparathyroidism." Patients with this condition have the clinical and chemical findings that one associates with hypoparathyroidism, but they fail to respond to parathyroid hormone and their parathyroid glands not only are not absent but may be hyperplastic. A second example is the failure of the American Indian to develop a beard. A patient presented himself, his only complaint being failure to develop a beard. Elaborate studies were carried out with uniformly normal results. Finally, someone had the wit to inquire about the patient's ancestry and found that he was part Indian.

**Oophorectomy.** The author feels that needless oophorectomy constitutes one of the greatest faults in medical practice. A normally functioning ovary, needless to say, is most essential for the future physical and mental well-being of a young woman. Satisfactory as replacement therapy is, it will not produce ova or be a substitute for motherhood.

There are two chief reasons for unnecessary ovarian surgery. The general surgeon does not realize that the normally functioning ovary is a cystic organ; he performs an exploratory laparotomy for some

# Diseases of the Ductless Glands

## Introduction

The author will not write the conventional introduction. He will not give the Greek derivation for the word hormone coined by Starling. He will not discuss the experiments of Claude Bernard which led to the concept of an internal secretion. He will not delve into the earliest beginnings of endocrinology which had as their *raison d'être* such ends as the procurement of a form of manpower safe for the harem, the salvaging of a male soprano voice for the choir, the increased palatability that a rooster attains when he turns into a capon, and so on. He will not trace experimental endocrinology from 1849 when Berthold studied the effect of the gonads on the secondary sex characteristics of fowl for the next hundred years down to 1949 when attention was focused on cortisone and its pituitary stimulator, adrenocorticotrophic hormone (ACTH). But why mention such prosaic facts in 1959 when we are well into the schizotomic era and rapidly approaching the author fears the posthistoric era? It would be more in keeping to mention that a pellet of stilbestrol can now replace pregnancy as a promoter of lactation in cows. No, the author will not even list the names of describers of various endocrine syndromes—from Addison with Addison's disease in 1855 down past the almost simultaneous elucidation of hyperparathyroidism in 1926 both by Mandel and by Du Bois to—well—to whom? The author thinks of no recent unmasking of a new syndrome. Are we leaving an era behind?

Instead, he will discuss what endocrinology is with special emphasis on what endocrinology is not, and then will comment on certain other aspects of the subject.

**What Endocrinology Is** Endocrinology is an indivisible division of internal medicine and has to do with certain glands or tissues which secrete highly specific substances into the blood stream for use by other tissues. The only important thought in this definition is contained in the word *indivisible*. It is impossible to separate endocrinology from internal medicine by the same token it is impossible to be an endocrinologist without being an internist. The physician who calls himself an endocrinologist and confines his interest to such unfortunate members of society as might appear in the sideshow of a circus never realizes that pneumonia, a broken leg, and a bad burn involve important changes in adrenal cortical function (cf. Alarm Reaction of Selye) that the disturbance in homeostasis occasioned by chronic renal insufficiency is ameliorated by a secondary hyperparathyroidism, that the somatotrophic action of testosterone propionate may be made use of in many conditions other than male hypogonadism, and so on.

The author resents the tendency to limit the scope of endocrinology to those disorders of the internal secretions which are not clearly understood. Thus, once some division of endocrinology such as diabetes is put on a firm footing, it is removed from the section on endocrinology to the section on metabolic diseases.

**What Endocrinology Is Not** Certain conditions often considered to be endocrine logical are probably not so at all.

First in order of frequency comes the fat boy who is slightly late in sexual development and whose genitalia are obscured by excess of fat. This patient nine times out of ten is labeled as having Frohlich's syndrome, whereas in point of fact he is just a fat boy whatever that is. If left alone, he will develop normally sexually.

## DISEASES OF THE THYROID GLAND

## Normal Physiology of the Thyroid Gland

The functions of the thyroid glands are to synthesize, store and secrete the thyroid hormones. The processes involved in these functions are complex and incompletely understood but it is now possible to measure the changes which are characteristic of various diseases of the thyroid. Modern knowledge of thyroid physiology can be traced largely to two new experimental tools: radioactive iodine and certain drugs such as thiourea which have specific effects upon the thyroid gland.

The metabolism of iodine is intimately involved in thyroid physiology. The daily ration of iodine which is normally between 100 and 250 micrograms is absorbed from the gastrointestinal tract as iodide. Thyroxine and triiodothyronine if ingested may be absorbed unchanged. The thyroid selectively concentrates iodide from the blood. This energy requiring process is specifically blocked by certain inorganic radicals such as perchlorate and thiocyanate. Trapped iodide is quickly oxidized and transferred to tyrosyl residues in peptide linkage within the thyroid parenchymal cells to form mono and diiodotyrosine. These iodinated residues in turn are condensed to triiodothyronine and thyroxine which are then stored in the thyroid colloid. The colloid is composed of a complex glycoprotein of high molecular weight (circa 600,000) called thyroglobulin which contains the iodinated amino acids as part of the amino acid sequence. It is degraded to its constituent amino acids by proteolytic enzymes which are thought to be activated by the thyrotropic hormone of the anterior pituitary. At the same time mono and diiodotyrosine are also released from peptide linkage; these substances do not reach the peripheral blood but are degraded by a potent deiodinating enzyme which is present in the thyroid parenchymal cells. Normally the thyroid releases 75 to 125 micrograms of hormonal iodine daily.

Thyroxine which reaches the blood is

transported in close association with a protein which has an electrophoretic mobility close to that of a globulin. A small fraction also is associated with albumin. Triiodothyronine is less closely bound to plasma protein. The quantity of hormonal iodine in the peripheral blood is normally between 3.5 and 5.0 micrograms per 100 ml. Probably more than 80 per cent of this is thyroxine and the rest triiodothyronine.

The biochemical nature of the action of the thyroid hormones on peripheral cells is unknown. *In vitro* studies suggest that thyroxine may cause a metabolic effect by dissociating oxidative phosphorylation so that oxidation proceeds without the concomitant formation of phosphate bond energy. The thyroid hormones are largely deiodinated by the peripheral cells and iodide is returned to the blood for recirculation. Some of the thyroxine and triiodothyronine are formed into their respective glucuronides and are secreted in the bile. The acetic acid derivatives of thyroxine and triiodothyronine have been detected in brain and kidney but their precise role in metabolism is not known.

Iodide is excreted by the kidney at a clearance rate of approximately 35 ml of plasma per minute. The thyroid clears iodide at a slightly less rapid rate under normal circumstances. The kidney does not alter its clearance rate over wide ranges of iodide supply but the thyroidal clearance is sensitive to the mean daily intake of iodide. Adjustment to a changed mean level of intake is not reached by the thyroid until many weeks have passed.

Thyroxine and triiodothyronine (3.5:3 triiodothyronine) are thought to be the definitive thyroid hormones and the only significant secretion products of the gland. There is evidence however that 3.3 diiodothyronine and 3.3.5 triiodothyronine are also secreted by the thyroid but these substances are extremely rapidly degraded. Thyroxine and triiodothyronine have the same physiological effects qualitatively but quantitatively there are striking differences. The effect of thyroxine is not ob-

sort of abdominal pain and finds nothing but cystic ovaries out they come For some reason the surgeon ■ never sued for mal practice because of this the story would be different if under somewhat analogous conditions castration were resorted to in the male

Metropathia hemorrhagica is the second big cause for unnecessary removal of the ovaries This interesting condition can be treated medically in almost all instances

The author disapproves of oophorectomy even after the menopause He feels that the ovary still functions to a certain extent after the periods have ceased and that one sees more severe osteoporosis after an artificial menopause than after a physiological one

**Fat Distribution** Considerable space has been wasted in textbooks and writings on endocrinology about the distribution of fat In the writer's opinion there are fat people and thin people but with one exception the distribution of fat is of no diagnostic significance The one exception is in Cushing's syndrome in which there is a tendency for the face to be round ( moon faced ) this roundness is probably due to a tendency to deposit fat in front of the ears However that a propensity to deposit fat around the hips or on the lower extremities or diffusely throughout the body or where you will has any diagnostic significance is most unlikely it almost certainly has nothing to do with pituitary disease

**Hirsutism without Virilism** Of the many thorns in the side of the endocrinologist the most aggravating is the patient whose life is made miserable by excessive hair growth on the face and elsewhere In only one case in ■ hundred can the physician find an endocrine fault and what is worse in only the small percentage of cases in which the hair is too much not only where it should not be but also where it should be can the physician save his ego by asserting with any degree of confidence that the condition is not endocrinologic The only treatment he can offer is symptomatic which in this instance means the removal of the excess hair The Wonder stoen helps in some patients but most end up by turning to the painful costly and not too successful method of electroly

sis For psychological reasons the physician must never mention the words beard or razor or anything which suggests masculinity It is probable that the best way to remove the hair is with a razor What is needed more than any other one thing is ■ razor in disguise e g an electric razor that has been camouflaged with some fancy embellishment and called an electric depilator "

**"Practical" versus "Theoretical" knowledge** The subject matter of this paragraph is applicable to all internal medicine but especially to endocrinology The author is frequently asked in giving ■ talk to make it "practical" and not too theoretical" By practical is usually meant therapeutic by theoretical is usually meant "fundamental" The author has no patience with such ■ philosophy One cannot possibly practice good medicine and not understand the fundamentals underlying therapy Few if any rules for therapy are more than 90 per cent correct If one does not understand the fundamentals one does more harm in the 10 per cent of instances to which the rules do not apply than one does good in the 90 per cent to which they do apply The same policy carries over to medical education There are those who advocate medical schools which will turn out practical physicians rather than theorists But they end by turning out a poorer grade of doctors As with eggs there is no such thing as ■ poor doctor doctors are either good or bad

15 and 50 per cent of an administered dose of  $I^{131}$  within twenty four hours. The maximal uptake is not reached until after twelve hours. Values above 55 to 60 per cent are seen in patients with thyrotoxicosis; patients with prolonged iodine deficiency; those who have recently stopped a prolonged period of medication with one of the antithyroid drugs; and in certain rare cases in which metabolic anomalies in hormonogenesis result in a hyperplastic gland with a high avidity for iodine. Rarely patients with unusually active glands turn iodine over so rapidly that the peak accumulation has been passed by twenty four hours.

Thyroid  $I^{131}$  uptake values below 15 per cent occur in hypothyroid states. Abnormally depressed values are also seen in patients who are receiving antithyroid drugs or who have been receiving medications containing iodide or thyroid preparations. The depressing effect on  $I^{131}$  uptake caused by iodide ingestion may not be relieved until many weeks after withdrawal in patients with normal thyroids but a high uptake may reappear in the thyrotoxic patient within a week after withdrawal. The depressed uptake may persist for several weeks after the iodide is stopped.

The rate of appearance of protein bound radioactive iodine in the serum after administration of a tracer dose also is used as an index of thyroid function. The result may be expressed either as the fraction of the dose per liter of serum or as the ratio of protein bound  $I^{131}$  to total  $I^{131}$  expressed as per cent. The latter is called the conversion ratio. The test has certain theoretical as well as practical disadvantages but in general is a reliable index. It may be abnormally elevated in patients who have undergone thyroidectomy or radioactive iodine treatment in the past.

**Other Tests of Thyroid Function.** The serum cholesterol is usually low in patients with thyrotoxicosis and high in patients with hypothyroidism. There is a wide normal range in the measurement itself and there is considerable error.

Since patients with certain types of hyperthyroidism may respond dramatically to administration of therapeutic doses of iodides this device has been used as a therapeutic diagnostic test. Too often however an equivocal result is obtained and other tests are made less reliable by the administration of iodides. The observation that thyroid function in patients with hyperthyroidism and diffuse hyperplasia of their glands (Graves disease) cannot be

easily suppressed by administration of thyroxine or triiodothyronine has provided the thyroid suppression test. Thus if administration of 150 micrograms daily of triiodothyronine for a week fails to suppress  $I^{131}$  uptake one concludes that the patient has Graves disease. This test is having an increasing vogue and appears to be reliable and helpful in differentiating patients with mild thyrotoxicosis from normal subjects.

Other tests may be of value in special circumstances. The responsiveness of the thyroid to thyrotropic hormone may help in the differentiation of athyreotic and pituitary myxedema. Thus a rise from low levels in  $I^{131}$  uptake and in serum concentration of protein bound iodine after a few injections of thyrotropin may indicate that the pituitary rather than the thyroid itself is at fault. Since patients with Hashimoto's thyroiditis may have circulating antibodies to thyroglobulin precipitation and complement fixation tests may have diagnostic value in this disease. The cephalin flocculation test may also be positive and diagnostically helpful in Hashimoto's thyroiditis. More specialized tests are employed in the diagnosis of certain rare cases of metabolic cretinism. For example it may be of interest to test the iodine binding capacity of the thyroid of such a patient by observing whether radiiodine in the gland is discharged after an oral dose of thiocyanate or whether diiodotyrosine is normally degraded after intravenous administration. These tests are not as yet routinely employed in the clinical laboratory.

served until two or more days after administration but the effect is maintained and only slowly lost after several days. The response to triiodothyronine may occur within six hours after administration and by thirty-six to forty-eight hours the response has disappeared. Thus the total response to the two drugs is about the same but that of triiodothyronine occurs more quickly and is initially greater. There is controversial evidence to suggest that the acetic acid derivatives of thyroxine and triiodothyronine have a much more rapid metabolic effect. The suggestion has been made therefore that thyroxine is initially degraded in order to exert its specific action.

The growth and function of the thyroid is under the control of the thyrotropic hormone secreted by the basophilic cells of the anterior pituitary. These cells in turn vary their secretion rate in response to the thyroid hormone concentration in the plasma. Thus a fall in the plasma concentration of thyroid hormone is countered by an increased secretion of thyrotropin which stimulates the thyroid to increase production of hormone. The pituitary is at least partly under hormonal control from centers in the hypothalamus.

## TESTS OF THYROID FUNCTION

A wide variety of laboratory aids are available in the assessment of the functional state of the thyroid gland. Since most of these tests measure different aspects of thyroid function it is usually advantageous to secure two or more tests when the diagnosis is in doubt.

**Basal Metabolic Rate** When properly performed this is a simple and reliable index of the thyroid function. It suffers the disadvantage that there is a wide normal range and that subjective factors may cause significant alterations in the readings. In certain patients in whom the rela-

bility of other tests has been obscured by medication the basal metabolic rate may provide the only guide to diagnosis or response to a therapeutic program. In addition to patients with hyperthyroidism elevated readings may be seen in those with malignant lymphoma, certain blood disorders, pheochromocytoma, asthma, congestive heart failure and in fever. There may be abnormally low values in Addison's disease and in malnutrition.

**Serum Protein Bound Iodine Measure**ment of the quantity of iodine which is precipitable with the plasma proteins is a generally reliable index of thyroid function but the chemical estimation is difficult. The normal range is from 3.5 to 8.0 micrograms per 100 ml. In addition to thyrotoxicosis abnormally high values may be seen after ingestion of large amounts of iodide and may persist for months after administration of iodinated substances used in the visualization of the gallbladder, bronchial tree and spinal canal. In patients with Hashimoto's thyroiditis and in other types of thyroiditis as well and also in patients shortly after administration of therapeutic doses of radioactive iodine elevations in the serum concentration of protein bound iodine may be observed but in contrast to normal much of this protein bound iodine is not extractable by acid butanol. Abnormally low serum concentrations are observed in hypothyroid states and during the twenty-four to forty-eight hours after the administration of mercurial diuretics because of the interference of mercury with the chemical analysis.

**Tests Employing Radioactive Iodine** Tests employing radioactive iodine are now widely available. The most commonly used is the thyroidal uptake. The technique varies among laboratories but usually the patient is given an oral dose of 10 to 20  $\mu$ c of  $I^{131}$  in water and the fraction of this which accumulates in the neck is measured twenty-four hours later. Appropriate corrections must be made for radiation absorption and back scatter and for the particular geometrical system which is used. Variations in the test include measuring at six hours or at forty-eight hours, plotting the accumulation by frequent measurements over the neck and assaying the amount of  $I^{131}$  which appears in the urine during the first two days after administration. More elaborate tests provide a measure of the thyroid clearance rate. Normally the thyroid accumulates between

Holland and in southern Ireland In the United States it is found in the Great Lakes area Minnesota Ohio and in the Pacific northwest

Experimentally certain foods such as soya bean and cabbage may block normal synthesis of thyroid hormones and thereby cause compensatory hyperplasia of the gland There is an unsubstantiated suspicion that these substances may play a role in the production or accentuation of endemic goiter It has been proved in a district of Tasmania that goiter of school children is related to ingestion of milk from cows fed on a species of kale Many other dietary and environmental factors have been suggested such as arsenic excessive calcium in the diet infection polluted water and so forth but there is no proof for any of these Proof of the validity and adequacy of the iodine deficiency theory has been the striking disappearance of endemic goiter in those areas where iodized salt has been introduced particularly in the United States and Switzerland

**Symptoms** Apart from gradual enlargement of the thyroid there may be few or no symptoms In the most severe endemic districts however patients with goiter may be lethargic and have retarded skeletal development and deafness In such areas endemic cretinism makes its appearance As the gland enlarges there may be laryngeal stridor on exertion and difficulty in swallowing Rarely paralysis of a recurrent laryngeal nerve occurs

When the endemic is mild the disease is confined to adolescent females who have small diffusely enlarged glands and to older women with small nodular goiters When deficiency of iodine is more severe goiter is seen also in males and at times in pre-adolescent children Physical findings except in severe cases are limited to the goiter in the neck This is diffusely enlarged in younger patients and becomes nodular as the disease progresses At times most or all of the goiter may lie sub-sternally Only in the most severe cases are clinical signs of hypothyroidism evident The basal metabolic rate is usually normal but studies with radioactive iodine have demonstrated the avidity of these glands for the isotope Thus the standard uptake tests are in the abnormally high range Continued administration of large doses of iodides to these patients may lead to the appearance of hyperthyroidism (Jod Basedow)

The relationship of endemic goiter to malignant change in the thyroid is contro-

versial The preponderant evidence seems to be that endemic goiter does not predispose to the development of cancer of the thyroid but this is a moot point

**Prevention** The use of iodized salt prophylactically was introduced by Marine and Kimball in 1917 in Akron Ohio Their remarkable studies were based on earlier investigations of Marine and have led to the world wide acceptance of iodide prophylaxis of this disease Techniques have varied with social and economic conditions In the United States salt is iodized to a concentration of one part in 10 000 whereas in Switzerland the salt is iodized to one part in 200 000 The World Health Organization recommends one part in 100 000 In other countries it has been found more convenient to administer iodides in candy once a week or several times a year More recently iodate has been used because of its greater stability in packages in humid areas It is just as effective as iodide The important fact is that goiter is prevented if it can be assured that the patient is receiving an average of at least 40 micrograms of iodide per day Thyroid hypertrophy results if the mean daily intake is less

**Treatment** Iodide is effective therapeutically only if it is administered shortly after the disease begins and before involutionary and cystic changes have occurred There is no advantage to giving more than approximately 5 mg per day since more than this is rejected by the thyroid Even when full daily doses of iodide are given regressive changes are slow in developing and there may be no effect until weeks or months have passed if ever Somewhat better results may be obtained by the administration of thyroid hormone in dosage of 0.1 to 0.3 mg daily Occasionally a goiter will be found to melt away dramatically if it is of recent origin

If treatment is necessary it will usually be found that surgical removal is required The surgical indications are increasing pressure symptoms and suspicion of malignant change Cosmetic reasons may also be sufficient warrant for surgical removal

## Simple Nonendemic Goiter

(Colloid Goiter Simple Struma  
Adolescent Goiter)

**Definition** Simple nonendemic goiter is defined as parenchymal hypertrophy of the thyroid which is not dependent upon dietary inadequacy of iodine

**Etiology** The cause or causes of this disease are largely unknown. Because it is most often seen in adolescent females, endocrine factors have been suggested but not proved. Since constituents of certain foods, especially of the cabbage family, may cause goiter by specifically inhibiting hormone synthesis, it has been thought that dietary factors might be responsible for some cases of sporadic goiter, and this has been proved in a few instances. Sometimes a familial incidence is recorded, suggesting that genetically determined metabolic factors may play a role. Indeed, there is evidence in certain cases to indicate that genetically determined enzymatic activity in the thyroid is limited and that goiter has resulted as a compensatory phenomenon.

**Signs, Symptoms and Course** The disease usually produces no symptoms except gradual enlargement of the thyroid. Often the enlargement of the thyroid is noticed only during the adolescent years and gradually disappears as the patient becomes older, but more often the disease gives way to nodular goiter in middle life and may progress to toxic nodular goiter in the sixth and seventh decades. As it progresses over the years, increasing nodularity and size may cause pressure symptoms. Malignant degeneration may occur, but the frequency is probably less than 2 per cent. There are usually no symptoms or signs of hypothyroidism.

**Laboratory studies** are not helpful. The metabolism test is usually normal, and measurement of radioactive iodine metabolism by these glands is usually within normal limits, as is the determination of the serum concentration of protein-bound iodine. Blood cholesterol is normal. Needle biopsy is often helpful in differentiating this disease from chronic thyroiditis, with which it is frequently confused.

**Treatment** Administration of iodide is of little or no value. Some cases, particularly early cases in young patients, may respond dramatically to desiccated thyroid. Whenever simple goiter is encountered in adolescents, it is probably advisable to administer desiccated thyroid or thyroxine

for several years until the growth stimulus whatever it may be has passed. Thyroid hormone is usually of little value in treatment of simple goiter, which has become nodular. Nonendemic multinodular goiter generally requires no treatment unless the growth is causing pressure symptoms or unless recent growth of a focal area in the nodular mass suggests malignant change. The nodular goiters of older patients tend to produce thyrotoxicosis. Since this change is gradual and often unrecognized by the patients, the principal manifestations may be reflected in the cardiovascular system. Whenever cardiac arrhythmias, congestive heart failure, or osteoporosis occurs in patients with nodular goiter, the suspicion of thyrotoxicosis must be entertained.

## Endemic Goiter

**Definition** Endemic goiter can be said to exist when a distinct enlargement of the thyroid gland can be detected in more than 10 per cent of the population. Since other kinds of thyroid disease may exist in an area where goiter is endemic, a diagnosis of endemic goiter rests necessarily upon exclusion of other possibilities.

**Etiology and Occurrence** Most authorities are now agreed that a deficiency of iodine in the soil and water is the principal cause of endemic goiter. The possibility remains that genetic and other factors may accentuate the sensitivity of certain patients to iodide deficiency. Endemic goiter is still found in the Alps—especially in the Austrian Tyrol—in the Himalayas, the Pyrenees, the Carpathians, the entire Andean chain and in the mountains of New Zealand. There are also endemic areas in central Africa, southern central China, and certain localized areas in Japan and Brazil. Endemic goiter is also seen in Finland.

tion is common. There may be an increase in the frequency of bowel movements but diarrhea occurs only in advanced and severe cases. Signs and symptoms of congestive heart failure may be observed in patients with severe thyrotoxicosis or long continued and neglected disease. This is particularly true of those patients with toxic nodular goiter whose symptoms of failure of the circulation may bring them to the attention of the physician. Usual doses of cardiac glycosides are often ineffective in completely controlling the heart rate and the congestive failure. Emotional lability especially in females is more often present than not. Menstrual flow is reduced in amount. Insomnia contributes to the fatigue. Patients with Graves disease occasionally mention that their eyes have become more prominent and at times complain of itching, burning, lacrimation and diplopia. This latter group of symptoms suggests the presence of what has been called the ophthalmopathic type of Graves disease wherein the ocular symptoms dominate the clinical picture.

The striking features of Graves disease may be recognized at first glance but more commonly than not the definitive physical findings must be sought in more subtle manifestations. Prominence of the eyes may be seen and the proptosis of the optic bulb can be measured. Signs of sympatheticotonia include lid lag, globe lag, diminished blinking and retraction of the upper and sometimes of the lower eyelid. Occasional patients have weakness or complete paresis of the extraocular movements. Patients with the advanced ophthalmopathic type of Graves disease may show the most menacing peribulbar edema, proptosis, chemosis, conjunctivitis and diminution in visual acuity. The skin is fine, velvety, warm and moist. There is a fine rapid tremor of the extended fingers and tongue which must be distinguished from the coarser tremors of Parkinson's disease, alcoholism and apprehension. The hair is fine. The thyroid may be scarcely enlarged or many times the normal size but it is always firmer than normal. It rises with swallowing. A bruit may be heard over the gland and a thrill palpated. Rarely a toxic thyroid may be so low in the neck as not to be felt but a diagnosis of thyrotoxicosis in the absence of a palpable goiter is hazardous. The pulse is quick and bounding, the systolic blood pressure is increased and pulse pressure widened. There may be a systolic scratch over the cardiac pulsation area. The rest of the physical exam-

ination is customarily normal except that occasionally patients with the exophthalmopathic type of Graves disease show circumscribed erythematous thickenings over the anterior surfaces of their shins and rarely over the dorsa of their fingers and hands. Weakness of the skeletal muscles may occasionally be so severe as to be easily demonstrated. Lymphoid hyperplasia and splenic enlargement are sometimes seen. Younger patients with Graves disease usually show no evidence of congestive heart failure and the cardiac rhythm is usually normal. In more severe cases and in patients with underlying heart disease, atrial fibrillation and flutter occur. The circulation is rapid, the failure of the circulation being of the "high output" type. Older patients with toxic nodular goiter may also show the characteristic findings of congestive heart failure with enlargement of the heart, various arrhythmias and fluid accumulation. Angina pectoris is not a common cardiac manifestation of thyrotoxicosis.

Patients with long-continued and severe thyrotoxicosis may enter a phase of the disease which has been termed thyroid crisis or storm. This is most often precipitated by trauma, especially in the neck.

## Hyperthyroidism

*(Thyrotoxicosis Toxic Goiter Exophthalmic Goiter Graves Disease Basedow's Disease)*

**Definition** Hyperthyroidism may be defined as the constellation of signs and symptoms which arises when there is an excessive concentration of thyroid hormones in the blood. It may result from excessive administration of thyroid hormone (thyrotoxicosis factitia) from diffuse hyperplasia and hypertrophy of the thyroid (parenchymatous toxic goiter Graves disease Basedow's disease) or from an overproduction of thyroid hormones by the autonomous nodules of toxic nodular goiter. All forms of hyperthyroidism are marked by an increased rate of tissue oxidation and by certain disturbances of the neuromuscular systems. In addition in Graves disease certain characteristic ocular abnormalities may be observed.

**Etiology and Pathogenesis** The cause of Graves disease has escaped detection. Many of the anatomical and functional changes which are observed in this malady can be reproduced in animals by administration of the thyrotropic hormone from the anterior pituitary. These observations have suggested that Graves disease can be traced to overactivity of the pituitary gland and in turn perhaps to stimulation from higher centers by way of the hypothalamus. Nevertheless measurements by the most sensitive methods have usually failed to disclose an increased concentration of thyrotropic hormone in the blood of these patients. Further the thyrotropic hormone in its purest form fails to cause the ocular manifestations which are characteristic of the human disease. A closely associated factor from the pituitary has been found which causes proptosis of the eye of the Atlantic sea minnow without stimulating the thyroid.

There is support from the clinic for the neurogenic theories of the origin of Graves disease. Often patients with this disorder relate the beginning of their symptoms to major emotional or traumatic crises in

their lives. It has yet to be proved that these factors are more than precipitating or indeed that they have been more than coincidental. The striking familial incidence of Graves disease has suggested a constitutional or genetic factor. There seems to be no support for toxic or infectious theories.

With the exception of the ophthalmic findings all the signs and symptoms of Graves disease can be attributed to excessive secretion of thyroid hormones. These include elevated basal metabolic rate, increased sweating, muscle wasting and weakness, tremor, increased bowel activity, increased appetite, rapid and irregular heart action, weight loss and apprehensiveness. The pathogenesis of the ocular manifestations and of the pretibial myxedema which sometimes accompanies them is even more obscure. These latter changes result from the deposition of highly polymerized mucopolysaccharides in the ocular muscles and in the interstitial tissues of the orbit and in the skin.

Patients with toxic nodular goiter do not develop ocular proptosis or periorbital swelling and edema, but the signs of sympatheticotonia such as lid lag and lid retraction may be observed. All symptoms can be attributed to chronic excessive secretion of thyroid hormones.

**Clinical Picture** Thyrotoxicosis may be seen in all grades of severity. It may begin explosively but more commonly the symptoms develop so gradually that the patient is scarcely able to date the beginning accurately. Physical or psychic trauma may initiate symptoms. Perhaps the most common symptom of all is fatigue. Quadriceps weakness may be particularly evident when the patient attempts to ascend or descend stairs. Rapid heart action and irregular beating of the heart are commonly experienced. More often than not there is an increase in appetite and at times this may be a pronounced symptom. Often satiety is quickly reached. Weight loss occurs in spite of increased food intake. In older patients and rarely in younger patients the appetite may be poor. Sometimes it may be so stimulated that an actual weight gain is recorded. There may be a fine tremor of the fingers and less often the patient complains of feeling tremulous all over. The handwriting may deteriorate. Most patients are intolerant of heat but close questioning may be necessary to elicit this fact with certainty. Excessive sweating is characteristic and at times itching of the skin occurs. Shortness of breath on exer-

tion is common. There may be an increase in the frequency of bowel movements but diarrhea occurs only in advanced and severe cases. Signs and symptoms of congestive heart failure may be observed in patients with severe thyrotoxicosis or long continued and neglected disease. This is particularly true of those patients with toxic nodular goiter whose symptoms of failure of the circulation may bring them to the attention of the physician. Usual doses of cardiac glycosides are often ineffective in completely controlling the heart rate and the congestive failure. Emotional lability especially in females is more often present than not. Menstrual flow is reduced in amount. Insomnia contributes to the fatigue. Patients with Graves disease occasionally mention that their eyes have become more prominent and at times complain of itching, burning, lacrimation and diplopia. This latter group of symptoms suggests the presence of what has been called the ophthalmopathic type of Graves disease wherein the ocular symptoms dominate the clinical picture.

The striking features of Graves disease may be recognized at first glance but more commonly than not the definitive physical findings must be sought in more subtle manifestations. Prominence of the eyes may be seen and the proptosis of the optic bulb can be measured. Signs of sympathetic cotoma include lid lag, globe lag, diminished blinking and retraction of the upper and sometimes of the lower eyelid. Occasional patients have weakness or complete paresis of the extraocular movements. Patients with the advanced ophthalmopathic type of Graves disease may show the most menacing peribulbar edema, proptosis, chemosis, conjunctivitis and diminution in visual acuity. The skin is fine, velvety, warm and moist. There is a fine rapid tremor of the extended fingers and tongue which must be distinguished from the coarser tremors of Parkinson's disease, alcoholism and apprehension. The hair is fine. The thyroid may be scarcely enlarged or many times the normal size but it is always firmer than normal. It rises with swallowing. A bruit may be heard over the gland and a thrill palpated. Rarely a toxic thyroid may be so low in the neck as not to be felt but a diagnosis of thyrotoxicosis in the absence of a palpable goiter is hazardous. The pulse is quick and bounding; the systolic blood pressure is increased and pulse pressure widened. There may be a systolic scratch over the cardiac pulsation area. The rest of the physical exam-

ination is customarily normal except that occasionally patients with the exophthalmopathic type of Graves disease show circumscribed erythematous thickenings over the anterior surfaces of their shins and rarely over the dorsa of their fingers and hands. Weakness of the skeletal muscles may occasionally be so severe as to be easily demonstrated. Lymphoid hyperplasia and splenic enlargement are sometimes seen. Younger patients with Graves disease usually show no evidence of congestive heart failure and the cardiac rhythm is usually normal in more severe cases and in patients with underlying heart disease, atrial fibrillation and flutter occur. The circulation is rapid, the failure of the circulation being of the "high output" type. Older patients with toxic nodular goiter may also show the characteristic findings of congestive heart failure with enlargement of the heart, various arrhythmias and fluid accumulation. Angina pectoris is not a common cardiac manifestation of thyrotoxicosis.

Patients with long-continued and severe thyrotoxicosis may enter a phase of the disease which has been termed thyroid crisis or storm. This is most often precipitated by trauma, especially in the neck.

FIG. 72. Typical Graves disease in a thirty-year-old woman. Note the goiter and the widened palpebral fissures.

region as following thyroid surgery in an inadequately prepared patient. Classically thyroid storm is a sudden and severe accentuation of all the typical findings in the disease. There are great restlessness, delirium, high fever, rapid tachycardia with arrhythmias, sweating, shock, persistent vomiting and dehydration. The mortality in patients with thyroid storm may exceed 66 per cent. During recent years more adequate treatment of thyrotoxic patients, better recognition and particularly better preoperative preparation have made this long dreaded complication a rarity. Most rarely of all patients may enter a stage of exhaustion which has been termed apathetic thyroid storm. This is characterized by apathy, extreme muscle weakness, disorientation, rapid tachycardia, collapse, shock and sometimes gastrointestinal hemorrhage.

**Laboratory Examinations.** Typically the basal metabolic rate is elevated in patients with thyrotoxicosis and the degree of elevation correlates with the severity of the disease. A wide range of normal values makes it possible for an occasional patient to have thyrotoxicosis and a basal metabolic rate which is in the upper limits of the normal range. The protein bound iodine concentration of the serum is elevated above 8.0 micrograms per 100 ml and returns to normal as the disease is treated. The degree of elevation forms only a rough guide to the severity of the disease.

The uptake of radioactive iodine by the hyperplastic gland is usually increased above 60 per cent. The absolute value of the uptake is not a reliable index of the severity of the disease. Occasional patients with small hyperfunctioning thyroid glands will turn over the radioactive iodine so rapidly that a normal or low normal twenty-four hour radioiodine uptake test may be obtained. Measurement over the thyroid within the first few hours following administration or measurement of the quantity of protein bound radioactive iodine in the blood will obviate this error.

In thyrotoxicosis there is a depression in the serum concentration of cholesterol. Slight glycosuria and hyperglycemia may result from an increased rate of absorption of glucose from the gut. There may be negative nitrogen, calcium and phosphorus balances and these may lead to severe demineralization in the bones in severe cases of long duration.

**Diagnosis.** Usually a diagnosis of thyrotoxicosis causes no particular difficulty. The symptoms of heat intolerance, weight

loss, excessive appetite and muscular weakness suggest the diagnosis which is confirmed by tachycardia, warm moist skin, hyperexcitability, widened pulse pressure and often ocular manifestations. The diagnosis is confirmed by the usual laboratory findings of elevated basal metabolic rate, increased uptake of radioactive iodine and an elevated serum concentration of protein bound iodine. There may be no ocular findings. Occasionally the patients present themselves with only or predominantly the symptoms and signs of congestive heart failure. This is particularly true in those of the older age group who have had nodular goiter for a number of years and in whom the slow progress of thyrotoxicosis is so subtle that damage to an aging heart has occurred before the other symptoms of thyrotoxicosis have come to the patient's attention.

Thyrotoxicosis should rarely be confused with other conditions. Anxiety states may mimic the hyperexcitability and the palpitations, tachycardia and tremor of neurocirculatory asthenia may resemble those of hyperthyroidism. However, the skin is cool and damp, the tachycardia disappears during sleep and the tremor is coarse rather than fine. The basal metabolic rate and other tests of thyroid function are within normal limits. Occasionally the symptoms of chronic alcoholism resemble those of thyrotoxicosis but the tremor is coarse and the laboratory data are normal except the basal metabolic rate which may be modestly elevated. Patients with pulmonary emphysema and fibrosis and with bronchial asthma sometimes show prominence of the eyes and may bear a superficial resemblance to patients with thyrotoxicosis in other ways such as weight loss, tachycardia, shortness of breath and sweating. Patients with Parkinson's disease may sweat excessively and may be intolerant of the heat but here the resemblance ends. Tachycardia and an elevated basal metabolic rate are seen in pheochromocytoma.

Although in the last analysis the diagnosis depends upon confirmatory laboratory data, these tests may be misleading. The use of iodide and iodinated dyes of all descriptions interferes with the radioactive iodine test and with the determination of the protein bound iodine in the blood. Mercurial diuretics also interfere with the determination of the protein bound iodine. Recent medication with antithyroid drugs makes difficult the interpretation of all tests of thyroid function.

Often the best course in confusing cases

is to withdraw all medication and to observe the patient closely over the succeeding weeks until the clinical and laboratory information becomes coherent. It seems safe to say that if the diagnosis is questionable there is seldom any danger to permitting withdrawal of all medication provided that the patient is kept under close observation.

In certain cases it may seem expedient to attempt a therapeutic diagnostic trial either with iodide or with an antithyroid drug. In rare cases the response may be sufficiently dramatic to establish the diagnosis with certainty but more commonly than not the use of this technique in diagnosis leads to confusing or uninterpretable laboratory data and to an unconvincing clinical result. Modern tools of laboratory investigation almost invariably provide a diagnosis except in those cases which have been previously confused by medication and then it is generally better to discard the medications and observe than to add to the confusion by another trial of medication.

**Clinical Course and Prognosis** The course of thyrotoxicosis varies widely among patients. In some the disease is explosive and leads within a few weeks to such profound changes that treatment is urgent. More commonly the disease proceeds more leisurely with ups and downs and occasionally after several months or years may remit entirely but these patients are always subject to recurrences. The prognosis for the untreated patient is not good. The gradual attrition against the cardiovascular system may result in congestive heart failure after months or a few years but the heart is not usually damaged permanently unless thyrotoxicosis is superimposed on some other form of heart disease. Malnutrition may pave the way for intercurrent infections.

Intercurrent infections may not be well tolerated and are to be avoided in the thyrotoxic patient since occasionally they may precipitate thyrotoxic crises. Generally the course of infections is more severe in the thyrotoxic patient and in turn accentuates the thyrotoxicosis. Infectious hepatitis may be particularly severe in the thyrotoxic patient.

The ophthalmopathic form of Graves disease presents a special problem. This manifestation of thyrotoxicosis also may be cyclic in nature but commonly the symptoms gradually subside and the appearance of the eyes returns toward normal. Occasionally the proptosis and in-

flammatory changes progress relentlessly to the point where surgical decompression of the orbit is necessary. Usually with care the patient can be tided over the active phases of the disease to enter a chronic state of fibrosis of the orbital contents without active progression. The patients may be left with proptosis and in some cases ophthalmoplegia.

**Treatment** Thyrotoxicosis may be successfully treated by several methods. These include surgical removal of the thyroid, radioactive iodine and protracted medical therapy with the antithyroid drugs or iodide. External irradiation of the thyroid gland has been largely abandoned but some patients can be successfully treated by this technique.

Iodine as the exclusive therapeutic agent is seldom employed in the treatment of Graves disease. The remission which may be achieved is usually incomplete and often unsustained. More often the involuting effect of iodine is sought in the preparation of the patient for subtotal thyroidectomy. In mild cases iodine may be used for ten days to two weeks as the sole preoperative preparative medication. More commonly the patient is prepared by administration of an antithyroid drug such as propylthiouracil until nearly euthyroid and iodide is added in the last few days before surgery in order to cause involution and decreased vascularity of the gland. Iodine is remarkably potent in producing its effect. As little as 5 mg per day may be sufficient to in-

FIG 73 Ophthalmopathic form of Graves disease in a thirty-six-year-old woman.

region as following thyroid surgery in an inadequately prepared patient. Classically thyroid storm is a sudden and severe accentuation of all the typical findings in the disease. There are great restlessness, delirium, high fever, rapid tachycardia with arrhythmias, sweating, shock, persistent vomiting and dehydration. The mortality in patients with thyroid storm may exceed 66 per cent. During recent years more adequate treatment of thyrotoxic patients, better recognition and particularly better preoperative preparation have made this long dreaded complication a rarity. Most rarely of all patients may enter a stage of exhaustion which has been termed apathetic thyroid storm. This is characterized by apathy, extreme muscle weakness, disorientation, rapid tachycardia, collapse, shock and sometimes gastrointestinal hemorrhage.

**Laboratory Examinations.** Typically the basal metabolic rate is elevated in patients with thyrotoxicosis and the degree of elevation correlates with the severity of the disease. A wide range of normal values makes it possible for an occasional patient to have thyrotoxicosis and a basal metabolic rate which is in the upper limits of the normal range. The protein bound iodine concentration of the serum is elevated above 8.0 micrograms per 100 ml and returns to normal as the disease is treated. The degree of elevation forms only a rough guide to the severity of the disease.

The uptake of radioactive iodine by the hyperplastic gland is usually increased above 60 per cent. The absolute value of the uptake is not a reliable index of the severity of the disease. Occasional patients with small hyperfunctioning thyroid glands will turn over the radioactive iodine so rapidly that a normal or low normal twenty-four hour radioiodine uptake test may be obtained. Measurement over the thyroid within the first few hours following administration or measurement of the quantity of protein bound radioactive iodine in the blood will obviate this error.

In thyrotoxicosis there is a depression in the serum concentration of cholesterol. Slight glycosuria and hyperglycemia may result from an increased rate of absorption of glucose from the gut. There may be negative nitrogen, calcium and phosphorus balances and these may lead to severe demineralization in the bones in severe cases of long duration.

**Diagnosis.** Usually a diagnosis of thyrotoxicosis causes no particular difficulty. The symptoms of heat intolerance, weight

loss, excessive appetite and muscular weakness suggest the diagnosis which is confirmed by tachycardia, warm moist skin, hyperexcitability, widened pulse pressure and often ocular manifestations. The diagnosis is confirmed by the usual laboratory findings of elevated basal metabolic rate, increased uptake of radioactive iodine and an elevated serum concentration of protein bound iodine. There may be no ocular findings. Occasionally the patients present themselves with only or predominantly the symptoms and signs of congestive heart failure. This is particularly true in those of the older age group who have had nodular goiter for a number of years and in whom the slow progress of thyrotoxicosis is so subtle that damage to an aging heart has occurred before the other symptoms of thyrotoxicosis have come to the patient's attention.

Thyrotoxicosis should rarely be confused with other conditions. Anxiety states may mimic the hyperexcitability and the palpitations, tachycardia and tremor of neurocirculatory asthenia may resemble those of hyperthyroidism. However, the skin is cool and damp, the tachycardia disappears during sleep and the tremor is coarse rather than fine. The basal metabolic rate and other tests of thyroid function are within normal limits. Occasionally the symptoms of chronic alcoholism resemble those of thyrotoxicosis but the tremor is coarse and the laboratory data are normal except the basal metabolic rate which may be modestly elevated. Patients with pulmonary emphysema and fibrosis and with bronchial asthma sometimes show prominence of the eyes and may bear a superficial resemblance to patients with thyrotoxicosis in other ways such as weight loss, tachycardia, shortness of breath and sweating. Patients with Parkinson's disease may sweat excessively and may be intolerant of the heat but here the resemblance ends. Tachycardia and an elevated basal metabolic rate are seen in pheochromocytoma.

Although in the last analysis the diagnosis depends upon confirmatory laboratory data, these tests may be misleading. The use of iodide and iodinated dyes of all descriptions interferes with the radioactive iodine test and with the determination of the protein bound iodine in the blood. Mercurial diuretics also interfere with the determination of the protein bound iodine. Recent medication with antithyroid drugs makes difficult the interpretation of all tests of thyroid function.

Often the best course in confusing cases

recurrence is extremely rare Depression of the bone marrow and malignant change in the thyroid have not been observed nor have untoward effects on the germ plasma been observed In spite of the absence of these effects but in view of the hypothetical risk of radiation carcinogenesis it is still customary in most clinics to limit radioiodine therapy to patients beyond the age of forty Younger patients are treated surgically unless there are specific contraindications For example radioiodine is used in younger patients who have complicating heart disease or who have had thyroid surgery in the past and in whom repeated surgery might carry an added operative hazard

Radioiodine has been most widely used in the treatment of Graves disease It can also be used successfully in the therapy of toxic nodular goiter but the results are less satisfactory Usually larger doses are necessary and failure of the initial dose to be effective is more common

The outstanding complication of radioiodine therapy is myxedema This has occurred in 10 to 20 per cent of treated patients Hyperthyroidism is temporary in some patients and if desiccated thyroid is withheld the patient will return to normal after a few weeks Usually however it will be necessary to treat indefinitely with 0.1 to 0.2 gm of desiccated thyroid

Thyroidectomy is an effective way of treating thyrotoxicosis in the suitably prepared patient Because of the availability of the antithyroid drugs there is now no excuse for a surgical approach to a thyrotoxic patient until the hyperthyroidism has been controlled Without control surgery of the hyperfunctioning gland is accompanied by a high incidence of thyroid crisis

At surgery approximately 2 to 3 gm of thyroid tissue are usually left in each side of the neck The hyperplasia which these remnants undergo in the postoperative phase is usually sufficient to provide enough thyroid hormone for the patient The frequency of postoperative myxedema depends in large part upon the amount of thyroid tissue which is left Most series have recorded an incidence of 5 to 10 per cent Within a five year period approximately 5 to 10 per cent of patients operated upon can be expected to show a recurrence of their disease The recurrence rate is doubtless dependent upon the extent of the subtotal thyroidectomy In order to prevent recurrence some surgeons perform a radical thyroidectomy with the expectation that the patient will require desic-

cated thyroid for the remainder of his life

Damage to a single recurrent nerve is not a serious complication of thyroid surgery and is often temporary It results in hoarseness and in inability to produce a sharp cough It is always well to examine the vocal cords both before and after operation If both nerves are severed an immediate and permanent tracheotomy is usually required Serious postoperative infection or hemorrhage is not often encountered

The parathyroid glands are often temporarily damaged during surgery Symptoms of tingling and tightness in the fingers and a positive Chvostek sign may appear within eight hours Mental depression and anxiety are common symptoms Calcium lactate 1.0 gm every four hours orally may be sufficient to control the hypocalcemia or it may be necessary to provide calcium intravenously and to give up to 50,000 or more units of vitamin D daily Dihydrotachysterol (AT 10) has little if any therapeutic advantage over vitamin D The parathyroids are permanently damaged only rarely

The choice of therapy in thyrotoxicosis depends upon the problems which the patient presents and the resources which are available Once the diagnosis has been established one can proceed cautiously toward the institution of the therapy of election Radioiodine is indicated for patients with diffuse hyperplasia of the thyroid in the age group beyond forty This includes perhaps two thirds of all thyrotoxic patients No preparation is needed unless the functional state of the thyroid has been altered by previous medication and in most cases the patient can be treated on an ambulatory basis Only when the disease is advanced or when there are cardiac or other complications will hospitalization be required Radioiodine will also be customarily the therapy of choice in younger patients with complicating heart or other diseases when surgery seems undesirable In most clinics at the present time younger patients who have no surgical contraindications are prepared as previously stated

Therapy of thyrotoxicosis by continuous administration of the antithyroid drugs is less effective because of the difficulty in maintaining precise control and the high recurrence rate after cessation of the drug Patients who are treated in this way must be followed closely on the program for a year or two If there is inadequate control or if recurrence is observed following cessa-

duce a full therapeutic remission. Customarily five drops of a saturated solution of potassium iodide are used twice daily. Medication with larger amounts gives no increased effect. The fall of the basal metabolic rate takes place at the same rate upon administration of iodide as after withdrawal of desiccated thyroid from a patient treated for myxedema. For this reason it is thought that iodine somehow prevents release of hormones from the gland by inhibiting the effect of thyrotropin. The problem of why iodide causes the return of the thyrotoxic patient to normal or nearly normal but fails to cause hypothyroidism has not been solved. Rarely the use of iodine results in myxedema and this usually is accompanied by growth of a large goiter.

Thiourea and its derivatives are effective therapeutic agents in the treatment of thyrotoxicosis. Since these drugs do not prevent the release of preformed hormone, their effectiveness is not as rapid as that of iodide. Usually within two to three weeks after beginning therapy the patient experiences a gradual amelioration of symptoms such as tachycardia, tremor and heat intolerance and an increased sense of well-being and strength. Patients with small glands may be completely freed of symptoms of thyrotoxicosis within six to eight weeks and rarely even sooner, whereas patients with large glands with much stored hormone may require the use of these drugs for eight to twelve weeks or more before achieving a remission. The effectiveness of these drugs in blocking the utilization of iodine in the thyroid is limited to a few hours. Accordingly for maximum effectiveness it is necessary that they be given every six to eight hours.

The antithyroid drugs may be used either in preparation for surgical removal of the gland or continuously for medical control of the disease. If thyroidectomy is the goal, the antithyroid drug is used until the basal metabolic rate is normal and the patient has begun to gain weight. The drug is continued and in addition the patient is given five drops of a saturated solution of potassium iodide daily for five or six days before operation. If he is to be treated continuously with medication, full doses are given until the patient is clinically euthyroid and then the dose is gradually reduced and the frequency of medication lessened. In this way treatment may be continued for six months to a year or longer and then withdrawn. All observers are agreed that approximately one half to two thirds of all patients who are treated in this way have

a recurrence within a few weeks to months after the medication is withdrawn. If this occurs the antithyroid drug can be reinstated or a different and more definitive plan of therapy undertaken. Rarely patients develop hypersensitivity to the antithyroid drugs of the thiourea group. There may be minor rashes but more serious complications such as granulocytopenia and febrile responses occur in about 1 per cent of the cases and jaundice has been reported. In the event of a reaction of hypersensitivity another of the antithyroid drugs may be tried since cross sensitivity is not common. For patients who require antithyroid medication and who cannot tolerate the drugs of the thiourea group, potassium perchlorate is a potent antithyroid substance. This may be used orally in doses of 300 mg every eight hours until the disease is controlled. The effect of perchlorate is lost if iodides are given.

Several members of the thiourea group are in common clinical use. These include propylthiouracil which is customarily given in doses of 100 mg every eight hours, methylthiouracil in the same dosage and 1-methyl-2-mercaptoimidazole in doses of 10 to 15 mg every eight hours.

Radioactive iodine was introduced in the therapy of Graves disease in 1942. Initially a short-lived isotope was employed but since 1946  $I^{131}$  with a half-life of eight days has been almost universally employed. The simplicity of the technique and the excellence of the results have been so outstanding that it has become the preferred form of therapy. The effectiveness of the isotope is due to its preferential location in the thyroid and to its beta-ray emission which profoundly alters the function of thyroid parenchymal cells. The degree of damage of a given dose is dependent upon the size of the dose, the uptake by the gland, the rate of turnover of the isotope, the radiation sensitivity of the cells and perhaps to other factors. Since few of these can be assessed with accuracy, the dosage is empiric. It has been found that excellent results can be obtained if the patient is given approximately 0.16 millicuries of  $I^{131}$  per gm of estimated thyroid weight. This plan will result in permanent remission after a single dose in approximately 75 per cent of patients. The remaining patients require a second and sometimes a third therapeutic dose. A repeat dose is not usually given until an interval of several months has made it evident that the initial dose was inadequate to control the disease. Once remission has been achieved

recurrence is extremely rare. Depression of the bone marrow and malignant change in the thyroid have not been observed nor have untoward effects on the germ plasma been observed. In spite of the absence of these effects but in view of the hypothetical risk of radiation carcinogenesis it is still customary in most clinics to limit radioiodine therapy to patients beyond the age of forty. Younger patients are treated surgically unless there are specific contraindications. For example, radioiodine is used in younger patients who have complicating heart disease or who have had thyroid surgery in the past and in whom repeated surgery might carry an added operative hazard.

Radioiodine has been most widely used in the treatment of Graves disease. It can also be used successfully in the therapy of toxic nodular goiter but the results are less satisfactory. Usually larger doses are necessary and failure of the initial dose to be effective is more common.

The outstanding complication of radioiodine therapy is myxedema. This has occurred in 10 to 20 per cent of treated patients. Hyperthyroidism is temporary in some patients and if desiccated thyroid is withheld the patient will return to normal after a few weeks. Usually however it will be necessary to treat indefinitely with 0.1 to 0.2 gm of desiccated thyroid.

**Thyroidectomy** — an effective way of treating thyrotoxicosis in the suitably prepared patient. Because of the availability of the antithyroid drugs there is now no excuse for a surgical approach to a thyrotoxic patient until the hyperthyroidism has been controlled. Without control surgery of the hyperfunctioning gland is accompanied by a high incidence of thyroid crisis.

At surgery approximately 1 to 3 gm of thyroid tissue are usually left in each side of the neck. The hyperplasia which these remnants undergo in the postoperative phase is usually sufficient to provide enough thyroid hormone for the patient. The frequency of postoperative myxedema depends in large part upon the amount of thyroid tissue which is left. Most series have recorded an incidence of 5 to 10 per cent. Within a five year period approximately 5 to 10 per cent of patients operated upon can be expected to show a recurrence of their disease. The recurrence rate is doubtless dependent upon the extent of the subtotal thyroidectomy. In order to prevent recurrence some surgeons perform a radical thyroidectomy with the expectation that the patient will require desic-

cated thyroid for the remainder of his life.

Damage to a single recurrent nerve is not a serious complication of thyroid surgery and is often temporary. It results in hoarseness and in inability to produce a sharp cough. It is always well to examine the vocal cords both before and after operation. If both nerves are severed an immediate and permanent tracheotomy is usually required. Serious postoperative infection or hemorrhage is not often encountered.

The parathyroid glands are often temporarily damaged during surgery. Symptoms of tingling and tightness in the fingers and a positive Chvostek sign may appear within eight hours. Mental depression and anxiety are common symptoms. Calcium lactate 1.0 gm every four hours orally may be sufficient to control the hypocalcemia or it may be necessary to provide calcium intravenously and to give up to 50,000 or more units of vitamin D daily. Dihydroxycholesterol (AT 10) has little if any therapeutic advantage over vitamin D. The parathyroids are permanently damaged only rarely.

**The choice of therapy in thyrotoxicosis** depends upon the problems which the patient presents and the resources which are available. Once the diagnosis has been established one can proceed cautiously toward the institution of the therapy of election. Radioiodine is indicated for patients with diffuse hyperplasia of the thyroid in the age group beyond forty. This includes perhaps two thirds of all thyrotoxic patients. No preparation is needed unless the functional state of the thyroid has been altered by previous medication and in most cases the patient can be treated on an ambulatory basis. Only when the disease is advanced or when there are cardiac or other complications will hospitalization be required. Radioiodine will also be customarily the therapy of choice in younger patients with complicating heart or other diseases when surgery seems undesirable. In most clinics at the present time younger patients who have no surgical contraindications are prepared as previously stated.

**Therapy of thyrotoxicosis by continuous administration of the antithyroid drugs** is less effective because of the difficulty in maintaining precise control and the high recurrence rate after cessation of the drug. Patients who are treated in this way must be followed closely on the program for 1 year or two. If there is inadequate control or if recurrence is observed following cessa-

tion of treatment it is wisest to resort either to radioiodine or to surgical removal of the gland

In only an occasional case is there sufficient muscle weakness or evidence of cardiac dysfunction to warrant bed rest. Better therapeutic results will be achieved during the active phases of the disease if activity is limited to a degree which does not result in fatigue. Insofar as possible emotionally disturbing factors should be removed from the environment. Digitalis is used if there is auricular fibrillation or congestive heart failure, but doses somewhat larger than those usually employed will be required. Sedatives are often helpful. A well balanced high caloric diet is required. Vitamin supplements, especially of the B group, are prescribed in severe cases.

The ophthalmopathic form of Graves disease presents special problems. The progress of the ocular findings is not necessarily related to the state or change of the thyrotoxic elements of the disease. Thus progressive ophthalmopathy may occur in thyrotoxic as well as in hypothyroid patients, and remissions are seen both as the patient becomes more thyrotoxic and as hypothyroidism is induced therapeutically. Hypothyroidism is to be avoided in patients with progressive ophthalmopathy. Thyrotoxicosis if present should be treated. The eyes should be protected by suitable glasses against bright sunlight and against dust and wind. Often it will prove helpful to have the patient sleep in a semi-sitting position. The inflammation and chemosis which mark a more severe case may be treated with a collyrium of hydrocortisone. Intensive diuretic therapy is of value in severe cases. Relentless proptosis with ulceration or threatened ulceration of the cornea and progressive loss of visual acuity are the usual indications for surgical decompression of the orbits. Roentgen therapy to the orbits, the pterygoid fossa or the pituitary is disappointing. Results are slow and may be no more than are seen in the natural fluctuations of the disease. There is no specific therapy for the ophthalmoplegia. On the theory that the ophthalmic syndrome is dependent upon a pituitary factor which can be suppressed by desiccated thyroid administration of this medication is advisable.

Thyrotoxic crisis is a major medical emergency. Bed rest and adequate sedation are essential. The patient should be treated with oxygen and if his temperature is dangerously elevated with ice bags or

alcohol sponges. Maximal control of the thyrotoxicosis is achieved by full doses of an antithyroid drug such as 1-methyl-2-mercaptoimidazole followed in a few hours by full doses of iodides. These medications can be given orally or parenterally if the patient is vomiting. Shock and dehydration are treated by parenteral replacement therapy with blood and balanced salt solutions. Any suspicion of infection requires use of antibiotic medications. Since adrenal failure may play some role in thyrotoxic crisis the patient should be supported with cortisone or prednisone. He should be digitalized in an endeavor to control the ventricular rate in the event of auricular fibrillation or congestive failure. The recent report that Rauwolfia alleviates certain peripheral manifestations of thyrotoxicosis including tachycardia suggests that a member of this group of drugs might be of value.

### Thyroiditis

A number of pathological conditions of the thyroid gland have been grouped under the term thyroiditis. Thyroiditis may be classified as acute suppurative, acute non-suppurative, subacute and chronic. Chronic thyroiditis is subdivided into Hashimoto's thyroiditis and Riedel's struma. In addition the thyroid may be involved by tuberculosis, syphilis and sarcoid.

Acute suppurative thyroiditis is encountered with the greatest rarity either as a result of blood borne infection with the ordinary pyogenic organisms or by extension along the fascial planes of the neck from infection above. It has been seen following infection or extraction of teeth

**Acute thyroiditis** is an inflammatory condition of the thyroid characterized by suddenness of onset. It frequently follows a mild upper respiratory infection. Some cases are thought to be caused by the virus of mumps. The disease may be asymptomatic except for a swelling of the thyroid but more commonly it is associated with exquisite tenderness of the gland rapidly enlarging goiter and accompanying systemic manifestations such as chills and fever. The radioactive iodine uptake test may be depressed to zero and there may be a transient elevation of the serum concentration of protein bound iodine. Analysis of the organic iodine of the blood may indicate that it is thyroglobulin rather than thyroxine. Antibodies against the patient's own thyroglobulin may make their appearance during the course of the disease. The erythrocyte sedimentation rate is elevated for many weeks. The disease follows an unpredictable course. It may last for only a few days or may extend over weeks and may recur one or several times only to subside again. Each exacerbation is usually less severe than the previous one. The disease may involve the entire gland but occasional focal areas may be involved first on one side and then on the other. Pathologically there is a focal or generalized inflammatory reaction replacing and destroying the parenchyma. Suppuration does not occur. The diagnosis is made from the signs and symptoms but needle biopsy may be necessary to establish the diagnosis.

Assessment of modes of therapy for so uncommon a disease has not led to agreement. In most cases symptomatic treatment with aspirin, ice bag and bed rest is all that is necessary. A few hundred r of x-ray therapy may produce remission in many cases. Though thyrotropic hormone, desiccated thyroid and antithyroid drugs have been advocated there appears to be little rationale for their use. Cortisone 100 to 200 mg daily suppresses the inflammation and almost invariably induces a subsidence of fever and evidence of inflammatory reaction. However the symptoms and signs often recur as soon as cortisone is withdrawn. The prognosis is good except only that some of these patients develop hypothyroidism and require thyroid hormone for maintenance thereafter.

**Subacute or pseudotuberculous thyroiditis** is a less well defined and less commonly encountered inflammatory disease of the thyroid which is characterized by protracted course, minimal to moderate symptoms and little fever or malaise. Patho-

logically there are destruction of the parenchymal epithelium and infiltration of the thyroid substance with an inflammatory exudate containing giant cells. This disease may be a variant of acute thyroiditis. Its etiology remains unknown.

**Struma lymphomatosa** described first by Hashimoto in 1912 is a chronic disease of the thyroid manifested clinically by progressive goiter with or without pressure symptoms. Pathologically a characteristic lymphocytic infiltration replacement of the thyroid parenchyma occurs. Recently it was shown that the patients have developed a sensitivity to their own thyroglobulin. Thus the lymphocytic infiltration into the thyroid is thought to represent the tissue reaction to an antibody antigen reaction proceeding within the thyroid itself. Just what initiates the process has not been made clear.

The disease is much more commonly seen in females. Usually they seek medical attention because of a mass in the neck or because of pressure symptoms. Clinically there are no abnormal findings except for the mass in the neck and evidence of hypothyroidism. The thyroid has a distinctive firm lobular configuration. It is not tender. Almost always there is thickening of the pyramidal lobe. Usually the standard tests of thyroid function are within normal limits. On occasion the radioactive iodine uptake and turnover may be slightly elevated. Analysis of the protein bound iodine of the serum often discloses that a significant fraction is thyroglobulin. Positive cephalin flocculation and colloidal gold tests may be obtained and a slight elevation in the serum gamma globulin concentration may be present.

There is usually a slowly progressive enlargement of the gland until symptoms may require its removal. Late in the disease there may be distinct evidence of hypothyroidism. Surgical treatment of Hashimoto's thyroiditis is unnecessary unless there are pressure symptoms or the goiter is cosmetically unacceptable. Early cases may respond to full doses of desiccated thyroid.

Perhaps the rarest form of thyroiditis is **Riedel's struma** or **igneus thyroiditis**. It is always seen in older patients. It develops insidiously and manifests itself primarily by pressure symptoms. Pathologically there is dense fibrosis and infiltration into the neighboring structures in the neck. The cause is unknown. Some observers think that it represents an end result of Hashimoto's thyroiditis but most authorities do not agree. The only known treatment is surgical removal.

## Thyroid Nodules and Malignant Disease of the Thyroid

Nodules in the thyroid always raise the question of cancer. When the gland is multinodular the problem is relatively simple because only a small fraction perhaps less than 2 per cent of these glands will show pathological evidence of malignant change. When there is history of recent growth of one of the nodules when one of them appears particularly firm or when there is satellite adenopathy one should suspect malignant disease.

Most pathologists are agreed that between 10 and 20 per cent of all single thyroid nodules are malignant. Some however question the pathological criteria which have been applied. They point to the low incidence of metastatic cancer of the thyroid as evidence against the malignant nature of single nodules. Metastatic malignant disease from the thyroid is indeed rare but perhaps not so rare as statistics would indicate because of the chronic and relatively benign nature of metastatic thyroid malignant neoplasms.

There is no reliable method short of surgical removal for distinguishing between benign and malignant thyroid tumors. The nodule which is thought to be solitary clinically is often found at exploration to be a cluster of adenomas or cysts. Most commonly the solitary nodule is composed of many small and large follicles with flattened epithelium and filled with colloid. Sometimes papillary infoldings predominate and the nodule is called a papillary adenoma.

the histological structure of which resembles fetal thyroid may be transition forms to frankly malignant neoplasms.

Carcinoma of the thyroid takes many different pathological forms and at times a variety of histological types are found in adjacent areas of the same tumor. The most common tumor is the papillary carcinoma. This is a slowly growing neoplasm which metastasizes first to the regional nodes in the neck and only later to the lungs bones and elsewhere. It is a more malignant and lethal disease in older patients. Treatment is surgical excision of the local lesion together with removal of the regional lymph nodes if they are suspected of being involved. Localized distant metastases may be removed if technically feasible. Pulmonary metastases from papillary carcinoma unlike the disease in the neck may be particularly susceptible to radiation therapy.

The so called benign metastasizing struma is not a benign disease but a slowly growing follicular carcinoma of the thyroid. There is always a primary lesion in the gland itself which satisfies the usual criteria of malignant change upon careful search by the pathologist. Most often the disease declares itself as a metastatic lesion in a distant bony structure such as the pelvis hip spine or skull. The distant metastasis pathologically resembles normal thyroid tissue. These metastases are removed when surgically feasible. They are the tumors which have been shown to take up significant amounts of radioactive iodine and accordingly are the ones which benefit from radioiodine therapy. There are case reports which record dramatic improvement in local symptoms. The disease under any circumstances is extremely indolent. After many months or more often after many years other more malignant and invasive metastases make their appearance.

Solid adenocarcinoma of the thyroid is a much more lethal and rapidly progressive disease than the types already mentioned. The disease may spread with considerable rapidity from the thyroid to distant sites such as liver lung and bone. It may also be found in the regional nodes. Surgical excision of the local lesion offers the best opportunity for cure. Deep x ray therapy also directed to the neck may be of more value in this type of thyroid cancer than in others.

The small cell carcinomas of the thyroid are usually extremely malignant often progressing to death within weeks or a few

months Temporary alleviation of the symptoms may be gained from x ray therapy but radioiodine has no role A rare case can be ablated surgically if the disease is found early enough

Other types of neoplasia within the thyroid are encountered with less frequency Hodgkins lymphoma may be found and metastases from tumors of lung large bowel kidney and elsewhere have been seen as well as plasma cell myeloma Epidermoid cancer of the thyroid is particularly malignant although exceedingly rare

In general it can be said that surgery offers the only satisfactory therapy for cancer of the thyroid It is frequently possible to excise local and distant lesions repeatedly in the course of the more benign neoplasms Radioiodine has proved disappointing in that few patients if any are cured by it and the symptomatic relief which can be achieved is limited to a small fraction of the cases Furthermore the technique is laborious time-consuming and expensive and highly undesirable effects on the bone marrow have been encountered Finally it should be noted that hypothyroid states are undesirable in the management of thyroid cancer because some of these tumors are dependent upon the thyrotropic hormone for growth and are stimulated to increased growth rate when the normal inhibition of thyrotropin production is withdrawn

## Hypothyroidism

**Definition** Hypothyroidism is a functional state which results when there is insufficient circulating thyroid hormone It is a result of anatomical absence or func-

tional insufficiency of the thyroid gland There is also a possibility that certain patients may respond inadequately to normal amounts of one or both of the thyroid hormones Hypothyroid patients may be classified as having cretinism juvenile myxedema adult myxedema and hypothyroidism without myxedema The clinical findings are determined by the duration and degree of thyroid failure and the time of life at which it occurs

**Etiology.** Cretinism results from thyroid deficiency in fetal or early neonatal life The diagnosis requires that there be retarded development in the skeleton and central nervous system The changes may be permanent and irreversible or not depending upon how early the diagnosis is made and the amount of damage which has occurred by the time therapy is instituted Endemic cretinism is seen in areas of the world where endemic goiter is found and its prevalence roughly parallels the severity of the endemic It is the result of an inadequate supply of iodine during critical growth phases of intrauterine and postnatal life Although the placenta concentrates iodide the maternal thyroid made available for iodide by iodide lack may take precedence over the placenta and over the developing fetus for whatever iodide is available Endemic cretinism accordingly occurs in families whose members already show evidence of iodine want

Sporadic cretinism is a rare condition which results from embryonal failure of the thyroid gland to develop Small islands of aberrant thyroid tissue may produce enough hormone during fetal life to forestall irreversible damage provided that therapy is begun early in postnatal life

Metabolic cretinism results from failure of thyroid hormone synthesis because of a biochemical abnormality in the production of hormone in the gland These patients are rare and the condition usually occurs as an hereditary disorder At least four distinct types have been described but the end result is the same in all viz hypothyroidism and goiter One type lacks the ability to oxidize iodide to iodine in the thyroid The thyroids of another group are unable to couple iodotyrosine residues together to form hormonal iodothyronines The patients belonging to a third type have a body wide lack of an enzymatic system which deiodates iodotyrosine These hormone precursors are lost from the body in the urine A fourth group of metabolic cretins secrete an abnormal iodinated protein from their thyroids into the blood

Juvenile myxedema differs from cretinism in that there is no permanent retardation of mental development. The disease begins in childhood it is not present at birth. In most cases it is attributable to destruction of the thyroid gland during the early years by unknown causes but in some it is due to failure of functioning aberrant remnants to produce sufficient thyroid hormone as growth progresses. Thus it is possible to demonstrate hyperfunctioning thyroid tissue in some of these subjects but the quantity of hormone in the peripheral blood is below normal.

The cause of primary adult myxedema is usually not known except in those patients in whom the thyroid gland is destroyed surgically or by radioactive iodine. There is evidence to suggest that in some cases destruction of the gland is the result of an autoimmune process similar to that which has been described in thyroiditis. Occasionally adult myxedema is seen as the end result of chronic thyroiditis. Usually only a fibrous remnant is found in the neck. This may contain a few isolated islands of acinar tissue. Occasionally the clinical picture of myxedema dominates the clinical findings in Sheehan's syndrome in which thyroid failure is traceable to pituitary destruction.

Hypothyroidism without myxedema may occur when the thyroid is incompletely destroyed. This occurs occasionally after radioiodine therapy or surgical ablation of the thyroid and occasionally in the course of thyroiditis. Confirming laboratory data may include a subnormal serum concentration of protein bound iodine and at times an increased uptake of radioiodine with rapid turnover by the surviving remnants. More often than not however by the term hypothyroidism without myxedema is meant a vague syndrome characterized by fatigue and other neurasthenic symptoms coupled with a low basal metabolic rate. It seems most probable that this condition has nothing whatever to do with the thyroid. It has also been suggested that certain patients are hypothyroid because of an inability to convert thyroxine into triiodothyronine in the peripheral tissues. Evidence for the existence of this syndrome is incomplete.

**Signs and Symptoms.** *Cretinism.* Typically the cretin is dwarfed and mentally retarded. Among the signs which may be observed as early as four weeks after birth are failure to feed properly, an enlarged and protruding tongue, umbilical hernia, thickening and drying of the skin, hyporeflexia and torpor. If the disease is recognized at this

stage therapy may permit normal development in some cases but in others irreversible changes have already taken place. Later the characteristic hoarseness of cry, the round face, the eyes set wide apart, the dark hair, the yellow scaly skin and constipation may suggest to the experienced observer the presence of cretinism. There is delayed dentition. Retarded bone age is one of the characteristic features of the disease. Juvenile or adult cretins present an unmistakable appearance. The hair is usually black. There may or may not be retarded genital development. They are characteristically phlegmatic and cheerful. Endemic cretins and cretins with metabolic cretinism are goitrous whereas sporadic cretins are athyreotic. A sporadic cretin never shows evidence of thyroid function by laboratory tests whereas often the endemic cretin will show normal thyroid function by radioactive iodine uptake test and by measurement of the serum concentration of protein bound iodine. These tests do not necessarily reflect the condition which existed in fetal life or early thereafter when the irreversible damage was done.

Juvenile myxedema differs little from adult myxedema except for evidence of retardation of bony growth. The facies may not show the characteristic features of established adult myxedema but these changes are apparent to a degree if looked for. The hair is coarse, the skin is dry and often there is hyperkeratosis pilaris. The skin is sallow and slightly yellow. Dentition may be delayed but the mentality is normal although cerebration may be slow. These patients may sometimes be thin because of poor appetite but more commonly they are moderately obese.

Adult myxedema exists in all degrees of severity depending upon the completeness and duration of thyroid failure. The patient usually has few complaints. These consist of intolerance to cold, dryness of the skin, constipation, a tendency to put on weight, dry hair and diminished vigor. The facies is pathognomonic. The hair is thin and coarse, the eyebrows thin, the skin cool, dry, scaly and thickened and the face puffy particularly around the eyes. The tongue is large. The pulse is slow and regular. The blood pressure in younger patients is normal but may be permanently elevated in older patients. The heart may be enlarged and there may be pericardial, pleural or abdominal fluid. Carotenemia gives the face a typical faintly yellow color. The reflexes show a characteristic slowness of the relaxation phase. The speech is slow and

coarse and mentation is retarded. Usually these patients are jolly but occasionally they are depressed and at times frankly psychotic. The circulation is slow as evidenced by the circulation time. The menses tend to be excessive and prolonged and often the bleeding can be shown by endometrial biopsy to be from a proliferative rather than a secretory endometrium. There may be a mild normochromic or macrocytic anemia. Vague pains in the extremities and in the back are common and stiffness of the joints is a frequent complaint.

The signs and symptoms of pituitary myxedema may be indistinguishable from those of athyreotic myxedema. The skin tends to be thin and finely crinkled rather than thickened but it may be necessary to resort to laboratory tests in order to distinguish between these two conditions.

**Diagnosis.** Hypothyroid states should be readily recognizable by attention to symptoms and from the characteristic features and activity of the patient. The basal metabolic rate is typically in the neighborhood of minus 40 per cent in patients with athyreotic myxedema. It may be somewhat lower in patients with pituitary myxedema. Radioactive iodine uptake is less than 10 per cent except in those patients with metabolic cretinism or endemic cretinism when it may be normal or high. The concentration of protein bound iodine in the serum is low and indeed the diagnosis cannot be made with certainty without this finding. The circulation time is slow. The electrocardiogram shows low voltage and flattened T waves. The cholesterol concentration in the serum is above 250 micrograms per 100 ml but may not be elevated in pituitary myxedema.

It is essential that hypothyroidism be recognized in the infant if it is present for thyroid deficiency during early critical phases of growth results in permanent retardation of mental and skeletal development. On the other hand it is important to guard against the overdiagnosis of hypothyroid states. Obese adolescents, tired middle aged women, patients with menstrual irregularities and children who are not progressing well in school often receive a gratuitous diagnosis of hypothyroidism. Administration of thyroid to these patients usually results in no significant clinical change. Many otherwise normal people show basal metabolic rates which vary from minus 20 to minus 30. These patients are best classified as hypometabolic without hypothyroidism. They respond transiently

or not at all to thyroid. The decision for treatment with desiccated thyroid should depend upon an accurately determined serum concentration of protein bound iodine.

It may be difficult to distinguish athyreotic from pituitary myxedema. The history and appearance of the patient may provide a clue. Evidence of normally functioning adrenals and gonads excludes a diagnosis of pituitary myxedema as does a finding of significant amounts of follicle stimulating hormone in the urine of a postmenopausal

FIG. 74. Typical athyreotic myxedema in a seventy-five-year-old man. The photographs were taken before (upper) and after (lower) therapy. (From Hertzog E. Practitioner 94:26 1915 By permission.)

female To confuse the problem further it must be said that patients with athyreotic myxedema of long standing may rarely have inactive adrenals and pituitary It is sometimes of value to attempt to stimulate the thyroid with thyrotropic hormone measuring the change in serum protein bound iodine and  $I^{131}$  uptake A positive response indicates that the thyroid is inactive because of pituitary failure

**Prevention and Treatment Cretinism** Endemic cretinism can be prevented by the use of iodized salt or other prophylactic measures in the endemic areas Other kinds of cretinism cannot be prevented but many of the consequences can be prevented by early recognition and vigorous treatment The following table indicates the desiccated thyroid dose schedule for children

AGE	DAILY DOSAGE
2 to 4 months	6 mg
4 to 8 months	12 mg
8 to 12 months	18 mg
12 to 24 months	25-50 mg
2 to 4 years	30-100 mg
4 to 12 years	60-200 mg

A safe rule would seem to be to increase the dosage until the patient shows the earliest signs of thyrotoxicosis and to maintain dosage at just below this level increasing it as increase in size warrants a higher dosage The same program applies to athyreotic cretinism and to metabolic cretinism Beneficial effects of treatment should be apparent within a week The cretinous infant will show a decrease in weight thinning of the skin increased responsiveness and improved feeding Shortly thereafter renewed hair growth may be observed Treatment of established cretinism in the older child or in the adult is not successful Not only is there no evidence of improvement in mentation but desiccated thyroid often makes these patients irritable and more difficult to manage

Children with *juvenile myxedema* respond quickly to thyroid hormones with improvement in mood and mentation and renewed growth In some cases administration of full doses of thyroid has precipitated a psychotic reaction Withdrawal of the medication and reinstitution at a lower dose level gradually building up to an adequate one is sufficient to overcome this difficulty Patients with early adult myxedema should be given full doses of 0.1 to 0.2 gm of thyroid without delay If the patients are elderly or if there is heart disease or angina

pectoris full doses of thyroid may increase the angina or precipitate fatal myocardial ischemia In older patients it will generally be found wisest to begin with doses of the order of 15 milligrams increasing by this amount each week until a full maintenance dose is reached

The changes in facies may be slow and full restoration of normal appearances may not be seen until several months have passed Patients generally report symptomatic improvement within a week and within three or four weeks they feel remarkably better Constipation is relieved they lose weight activity and energy improve and sensitivity to cold vanishes

Patients with *pituitary myxedema* must be treated with extreme caution since it has been shown that the adrenal insufficiency which these patients have is much accentuated when thyroid function returns to normal Full doses of thyroid given at once have precipitated Addisonian crisis in a few cases If the diagnosis is made the patient should be treated cautiously with thyroid and in addition should receive supporting doses of adrenal cortical substance

At the present time there are few recognized occasions in which there is an advantage to be served by medication with triiodothyronine It is possible that a rare patient with extreme hypothyroidism of long standing and with congestive heart failure might be treated with this medication in a desperate effort if a few days delay in response might seem dangerous There appears to be no advantage to giving thyroxine rather than desiccated thyroid provided that a USP preparation of the latter is employed

## DISEASES OF THE PARATHYROID GLANDS

**Introduction** Diseases of the parathyroid glands include primary hyperparathyroidism and hypoparathyroidism. For clinical purposes the latter includes "pseudohypoparathyroidism" although there is evidence that this is in reality an "end organ" disease rather than a true parathyroid disease. Secondary hyperparathyroidism is thought to play a part in the pathological physiology of osteomalacia—a condition in which the parathyroid glands are found to be hyperplastic. This is further discussed in the chapter on Osteomalacia. In renal glomerular insufficiency with elevation of the serum inorganic phosphate\* and depression of the serum calcium parathyroid hyperplasia is almost constantly seen. Some investigators attribute the osteitis fibrosa of this condition to secondary hyperparathyroidism, others to the renal failure *per se* (See Osteitis Fibrosa Cystica Generalisata). Space does not permit a discussion of the theoretical issues involved. However there is general agreement as to the pertinent practical consideration. Removal of parathyroid tissue is not of benefit in renal osteitis but rather the reverse.

This section is devoted to primary hyperparathyroidism, hypoparathyroidism, pseudohypoparathyroidism and tetany.

### PRIMARY HYPERPARATHYROIDISM

**Definition** Primary hyperparathyroidism is a condition in which chemical abnormalities of the serum and extracellular fluid result from overproduction of parathyroid hormone. Osteitis fibrosa cystica generalisata may or may not be present.

**Etiology** The immediate causes of primary hyperparathyroidism are single or multiple adenomas of the parathyroid glands, primary hypertrophy and hyperplasia of all parathyroid tissue and carcinoma. As the name implies the primary hypertrophy and hyperplasia is an entity distinct from the secondary hyperplasia seen with osteomalacia and renal failure. If it involves a "tropic stimulus" the source or nature of such stimulus is entirely obscure.

Hereafter the serum inorganic phosphate will be here termed the serum phosphorus for the sake of brevity.

Available evidence is strongly against the existence of pituitary parathyrotropic hormones. The cause of adenoma formation is also obscure. The relatively common association of pancreatic islet cell tumors and pituitary tumors with those of the parathyroid suggests a common etiological factor but throws no light on what it may be.

**Incidence** Primary hyperparathyroidism is a relatively rare disease. After the chemical and clinical criteria for diagnosis had been established and cases were being actively sought for at the Mayo Clinic and the Massachusetts General Hospital it required twenty years for each clinic to accumulate 100 cases. Adenomas were found in approximately 90 per cent of these and primary hyperplasia and hypertrophy in 10. Carcinoma is extremely rare. Adenomas appear about twice as frequently in women as in men.

**Morbid Anatomy** Adenomas vary greatly in size ranging from minute tumors barely visible macroscopically to large growths displacing the esophagus, easily palpable *in vivo* and resembling thyroid nodules. With primary hyperplasia and hypertrophy the weight of the combined glands has ranged from 2 to 70 gm. with the upper glands quite consistently larger than the lower.

Microscopically the functioning adenomas are composed of chief cells, water clear (wasserhelle) cells, admixtures of the two and less commonly of pale oxyphil cells. Among the chief cells considerable variability in nuclear size with giant nuclei and multinucleated cells are not infrequent and are not criteria of malignancy. With primary hyperplasia all the parathyroid cells are much larger than wasserhelle cells and are also clear.

When the bones are affected they show osteitis fibrosa cystica generalisata as discussed in the section on Diseases of Bones.

When the kidneys are affected they may develop nephrolithiasis or nephrocalcinosis both frequently complicated by pyelonephritis.

**Pathological Physiology and Chemistry** As a result of overproduction of parathyroid hormone by the adenomatous or hypertrophied glands there ensues (1) a decrease

in renal tubular phosphorus reabsorption and (2) a decrease in serum phosphorus. This results in a relative undersaturation of the extracellular fluids with respect to calcium phosphate with the result that (3) there is a rise in serum calcium. If the calcium intake is adequate and the additional calcium available in the gastrointestinal tract the bones may not be affected. If it is inadequate *osteitis fibrosa generalisata* frequently develops. As a result of the rise of serum calcium (4) the urine calcium rises. An effect of the parathyroids directly on bone independent of the renal effect has been established. This suggests that the *osteitis fibrosa* may be a direct effect of parathyroid hormone. The majority of cases of hyperparathyroidism now being recognized however have normal bones.

The cardinal biochemical signs of primary hyperparathyroidism are a lowered serum phosphorus, an elevated serum calcium and an elevated urine calcium. (A low calcium diet is generally employed for at least three days to evaluate urinary calcium excretion. A low phosphorus diet frequently exaggerates all three signs in borderline cases.) When the bones are affected there is in addition an elevated serum alkaline phosphatase. (The urine phosphorus is not of diagnostic value after a steady state of disease has been reached.)

The signs of primary hyperparathyroidism become more difficult to interpret with the appearance of renal failure, a very common sequela if treatment is not instituted. Renal failure results in (1) a rise in serum phosphorus, (2) a relative supersaturation of the extracellular fluid with respect to calcium phosphate, (3) a fall of serum calcium and (4) a fall of urine calcium. It is apparent that a point will be reached when the diagnosis can no longer be made. At this point however removal of the tumor does little to improve the patient.

A further difficulty in the diagnosis of primary hyperparathyroidism arises from the finding that some patients have hypophosphatemia without accompanying hypercalcemia (Bogdonoff *et al*). It has been suggested that the parathyroid glands may elaborate two distinct hormones, one specifically inhibiting renal tubular reabsorption of phosphate, the other directly mobilizing bone substance.

**Symptoms.** Symptoms in primary hyperparathyroidism may result from the hypercalcemia, the hypercalciuria and the bone disease when it is present. Hypercalcemia results in anorexia, weakness, fatigability, difficulty in swallowing, nausea, vomiting,

constipation and hypotonicity of the muscles and ligaments, the last at times resulting in striking double jointedness. These are presumably a reflection of the known effects of hypercalcemia in depressing the sensitivity to electrical stimuli of ganglia and peripheral nerves. The latter can be demonstrated directly by the use of Erbs test. Shortening of the Q-T interval in the electrocardiogram is found in some cases. Two lesions in the eyes result from hypercalcemia—band keratopathy in which bands of opaque material are found beneath Bowman's capsule in lines parallel to and within the limbus, especially in the palpebral fissure and conjunctival crystals located medially and laterally to the limbus, also in the palpebral fissure. Both lesions often require a slit lamp for recognition.

Hypercalciuria may result in nephrolithiasis and the appearance of calcium oxalate or calcium phosphate stones is often the presenting symptom of the disorder. In other cases nephrocalcinosis may result with progressive renal damage. Infection of the urinary tract is common with both complications.

The bone disease when it occurs is *osteitis fibrosa cystica generalisata*. It is dealt with in the section on Diseases of Bones. Of special value in diagnosis are the loss of lamina dura about the teeth, the finding of subcortical bone resorption and the presence of "cysts" and "brown tumors," especially the epulis of the jaw.

**Differential Diagnosis.** Hypercalcemia is found with vitamin D overdosage, with certain bone diseases and associated with renal damage with prolonged excessive intake of calcium and alkali. In all of these the history is of paramount importance. In all of them the serum phosphorus is characteristically normal (although it may rarely be depressed with hypervitaminosis D). In osteoporosis the serum alkaline phosphatase is normal and in Paget's disease the x-ray picture is usually diagnostic. Hypercalcemia and hypercalciuria are also often found in multiple myeloma and in sarcoidosis. In these diseases the serum phosphorus is characteristically normal and the serum globulin frequently elevated. The serum alkaline phosphatase is almost always normal in spite of bone disease in myeloma and is generally normal in sarcoidosis. Metastatic malignancy in bone may produce hypercalcemia and resemble hyperparathyroidism closely as the serum phosphorus although generally normal may be depressed. In this as in all the above disorders a normal lamina dura about the

*teeth* helps to exclude hyperparathyroidism as the cause of the bone disease

Hypercalciuria is characteristic of all hypercalcemic states except that due to prolonged excessive intake of calcium and alkali. Hypercalciuria without hypercalcemia occurs in "idiopathic hypercalciuria," a renal disease often accompanied by coccal infection and in "renal tubular acidosis." In neither is the serum calcium elevated in the latter metabolic acidosis is present. When metabolic bone disease occurs in these conditions it is osteomalacia; the reader is referred to the article on the subject.

The differential diagnosis of *osteitis fibrosa cystica* is discussed in the appropriate place.

**Prognosis.** Primary hyperparathyroidism responds very satisfactorily to surgery. The frequency with which a second adenoma occurs in patients from whom one has been removed is greater than that with which primary hyperparathyroidism occurs in the population at large. When primary hyperplasia and hypertrophy has been present (and partial resection done), persistence of hypercalciuria and recurrence of hypercalcemia are common.

**Treatment.** The treatment of primary hyperparathyroidism is surgical. Search for adenomas may involve dissection of the mediastinum as well as the neck. Adenomas should be removed *in toto*. With primary hyperplasia and hypertrophy (the presence of which should be confirmed by frozen section), small (ca. 250 mg.) sections of two glands with blood supply should be left and the rest removed. Postoperatively severe tetany may be expected where there has been bone disease. It may require vigorous therapy with calcium by vein (e.g. 30 ml. of 10 per cent calcium lactate in 1000 ml. of normal saline) and by mouth (e.g. 6 teaspoons calcium lactate a day) and with vitamin D by mouth (e.g. 50,000 units a day) until the bone disease is healed. Therapy must then be promptly stopped before it results in hypercalcemia.

### HYPOPARATHYROIDISM

**Definition.** Hypoparathyroidism is a condition in which chemical abnormalities of the serum and extracellular fluid result from underproduction of parathyroid hormone.

**Etiology.** The commonest cause of hypoparathyroidism is the inadvertent removal of or damage to parathyroid tissue during thyroid surgery. The resulting disease may

be temporary if enough tissue was left or if edema and hemorrhage were precipitating factors. Rarely hypoparathyroidism appears without apparent cause. Some cases are preceded by acute systemic infections; others are accompanied by mild infection of mouth, skin and nails with monilia. (It is not clear whether the monilia is a cause or a result of the disease.) In the latter group, familial incidence has been reported. The disease tends to develop in children under fifteen or in adults over forty and is rare between these ages for reasons not apparent. The frequency of its coexistence with Addison's disease is significantly above the probability of chance.

**Incidence.** "Idiopathic" hypoparathyroidism is a rare disease; only 34 cases had been reported by 1946. The incidence of postoperative hypoparathyroidism in various clinics naturally varies.

**Morbid Anatomy.** In "idiopathic" hypoparathyroidism the parathyroid glands have been reported to show complete or almost complete replacement of parenchymal tissue by fat. The finer blood vessels of the brain, especially those of the basal ganglia, may be surrounded by hyaline deposits which calcify. The bones may be abnormally dense.

**Pathological Physiology and Chemistry.** As a result of a decrease in parathyroid hormone secretion, there ensues (1) an increase in renal tubular phosphorus reabsorption, (2) a rise in serum phosphorus, and (3) a fall in serum calcium. As a result of the fall in serum calcium, (4) the urine calcium falls, reaching essentially zero at serum levels below 7 mg. per 100 ml.

The cardinal biochemical signs of hypoparathyroidism are thus an elevated serum phosphorus, a lowered serum calcium, and a lowered urine calcium. (The urine calcium is occasionally normal or even elevated in hypoparathyroidism—a phenomenon often associated with coccal pyelonephritis or prolonged calcium chloride medication.) The lowered serum calcium results in increased excitability of peripheral nerves and ganglia, and hence in tetany and symptoms referable to hyperactivity of the autonomic system.

**Symptoms.** Most of the symptoms in hypoparathyroidism can be explained as results of the hypocalcemia; a few are unexplained. The most prominent manifestation of hypocalcemia is *tetany*. The first sign of this is often a sensation of numbness and tingling in the fingers and toes.

or about the lips. Laryngeal stridor with prolonged crowing inspiration, dyspnea and cyanosis are not infrequently seen occasionally leading to a mistaken diagnosis of vocal cord paralysis. As the tetany becomes more severe cramps of individual muscles and finally tonic contractions of muscle groups appear. In the hand and arm this results in the characteristic "ac coucheurs" position. Gastric pain, nausea and vomiting may accompany severe tetany. Generalized convulsions have frequently been described with severe hypoparathyroidism. In some cases there are an aura, tongue biting, urinary and fecal incontinence and post seizure coma and electroencephalograms support the impression that hypocalcemia is acting to trigger a pre-existing grand mal. Others in which both the seizure pattern and the electroencephalograms are atypical presumably represent a direct effect of hypocalcemia on the central nervous system. In all great improvement occurs when the hypocalcemia is eliminated. The differential diagnosis of tetany is dealt with below.

**Papilledema and increased intracranial pressure** are relatively frequent accompaniments of hypoparathyroidism. They disappear with therapy. Calcifications about the smaller vessels of the brain especially those of the basal ganglia often visible in skull x-rays are commonly seen in hypoparathyroidism. These do not regress with therapy. Neither of these lesions is found with hypocalcemia of other cause. Cortical cataracts are common in hypoparathyroidism and in other disorders involving hypocalcemia. The underlying mechanism for all these lesions is obscure.

Defects in ectodermal structures that may be found in hypoparathyroidism involve the teeth, nails, skin or hair. When hypoparathyroidism develops before the permanent teeth are mature they may show shortening and malformation of the enamel organ and shortening of the roots. The nails which may be malformed and brittle are sometimes infected with moniliasis as already mentioned. The skin is sometimes coarse and dry, the head hair patchy and thin, the eyebrow axillary or pubic hair may be scant or absent.

**Diagnosis.** A number of clinical tests may be employed to reveal the presence of latent tetany. Chvostek's sign is sought by tapping the finger over the facial nerve. A positive response consists of twitching of the muscles of the mouth and in severe cases of the nose and eyelids. A positive Chvostek's sign is usually but not

invariably present in tetany. A positive response occurs commonly in normal persons. Trousseau's sign is sought by producing ischemia to peripheral nerves by inflating a pressure cuff on the arm above systolic pressure for 3 minutes. A positive response is frequently elicited in patients with latent tetany. Erbs sign is sought by applying a galvanic current to the skin over a peripheral motor nerve and measuring the minimal current necessary to produce a muscle contraction upon cathode opening. With latent tetany a response appears with 5 milliamperes or less.

The characteristic serum values have been discussed. The electrocardiogram may show a prolonged Q-T interval with hypocalcemia.

The combination of increased intracranial pressure, papilledema and a history of convulsions in hypoparathyroidism has often led to a mistaken diagnosis of brain tumor. The relationship of epilepsy to tetany has been discussed.

**Prognosis.** In the hypoparathyroidism which follows thyroid surgery recovery often occurs even after weeks or months. Therapy should be carefully withdrawn at intervals in such cases until it is clear that no recovery will ensue. Idiopathic hypoparathyroidism requires continuous therapy and if this is adequate new cataracts should not develop. The prognosis of classic or atypical epilepsy in hypoparathyroidism is excellent if adequate therapy can be maintained.

**Treatment.** Acute hypocalcemic tetany requires prompt treatment with calcium intravenously (e.g. calcium lactate 10 per cent solution 10 to 30 ml intravenously in 1000 ml normal saline) given as often as necessary to control symptoms. Simultaneously calcium (e.g. calcium lactate 4 gm 4 times daily) and vitamin D (e.g. 50,000 units daily) should be started by mouth. The dosages should be reduced when the serum and urine calcium are brought to normal and maintained in quantities found adequate to keep them so. The Sulkowitch test for urine calcium which the patient can perform provides a useful index of the adequacy of therapy. AT 10 (Hytakerol) may be used (e.g. 0.5 to 1 ml orally each day) in place of vitamin D for maintenance therapy. It has the advantage of more rapid action, the disadvantage of greater cost.

#### TETANY

The symptom complex of tetany and the diagnostic tests for latent tetany have been

Schema for the Classification and Differential Diagnosis of Tetany

CAUSE	SERUM				URINE	
	Ca	P	pH	CO <sub>2</sub>	Ca	pH
<b>Hypocalcemia</b>						
Low Ca intake	low	low	normal	normal	low	indeterminate
High intestinal Ca loss						
1 Vitamin D lack	low	low	normal	normal	low	indeterminate
2 Sprue	low	low	normal	normal	low	indeterminate
3 Diarrhea	low	low	normal	normal	low	indeterminate
High urinary Ca loss						
1 Essential hypercalcaemia	low	low	normal	normal	high	indeterminate
2 Renal tubular acidosis	low	low	low <sup>1</sup>	low	high	high
Elevated serum P						
1 Hypoparathyroidism	low	high	normal	normal	low	indeterminate
2 Glomerular insufficiency	low	high	low <sup>1</sup> or normal	low or normal	normal	indeterminate
3 Excessive ingestion	low	high	normal	normal	low	indeterminate
<b>Alkalosis</b>						
Respiratory	normal	normal	high	low or normal	normal	high
Metabolic						
1 Excessive alkali intake	normal	normal	high	high	normal	high
2 Persistent vomiting	normal	normal	high	high	normal	high
3 Excessive H <sup>+</sup> loss to cells and urine	normal	normal	high	high	normal	low → high <sup>2</sup>

Ca = Calcium      P = Inorganic phosphate      CO<sub>2</sub> = Carbon dioxide content<sup>1</sup> Note that in renal tubular acidosis and in renal insufficiency the serum acidosis tends to oppose the effect of hypocalcemiaExcessive H<sup>+</sup> loss with high pH may occur when urinary NH<sub>4</sub><sup>+</sup> is high

discussed under hypoparathyroidism. The present section is devoted to its etiology and differential diagnosis.

Tetany may be precipitated by hypocalcemia or alkalosis or both. Whereas low magnesium tetany has been described its extreme rarity renders it negligible from the clinical point of view. Tetany has frequently been observed with potassium deficiency even without the commonly associated alkalosis. As intracellular acidosis is characteristic of potassium deficiency this suggests that the difference between extra- and intracellular pH may be important in the etiology of tetany. In the accompanying table are summarized the causes of tetany with the essential laboratory data.

The causes of hypocalcemia may be divided into those in which the calcium intake is inadequate, those in which gastrointestinal calcium loss is excessive, those in which urinary calcium loss is excessive, and those in which the serum phosphorus is elevated (and the serum calcium depressed).

Inadequate intake of calcium as a cause of hypocalcemia probably does not occur in the United States. Excessive calcium loss via the gastrointestinal tract occurs in hypovitaminosis D, in "resistance to vitamin D" in the sprue syndrome in which vita-

min D and calcium soaps are lost because of steatorrhea, and in severe diarrhea in which calcium-containing secretions are lost. In all these conditions the tetany should respond to measures designed to increase calcium absorption, e.g., vitamin D. Calcium salts control of diarrhea. Excessive calcium loss via the kidneys occurs in "essential hypercalcaemia" and in "renal tubular acidosis" but tetany is rare in these conditions.

Elevated serum phosphorus and lowered serum calcium are found in hypoparathyroidism and in glomerular insufficiency. In the former calcium is usually absent from the urine; in the latter urinary calcium is often decreased but seldom absent. The two conditions are generally easily distinguished by the presence or absence of other signs of renal failure, e.g., nitrogen retention. The intravenous injection of 200 units of parathyroid extract should clarify the differential diagnosis if any doubt remains. This results in marked phosphaturia in hypoparathyroidism (but see the section on Pseudohypoparathyroidism) and in virtually none in renal failure. In infants fed cows' milk, hyperphosphatemia with hypocalcemia and tetany has been reported in the absence of renal failure. Here the amount of phosphorus fed exceeds the amount filtered by the glomeruli at normal

serum levels. In glomerular insufficiency the tetany should respond to measures designed to lower the serum phosphorus *e.g.* oral aluminum hydroxide and raise the serum calcium *e.g.* vitamin D. Alkali therapy for correction of acidosis may have to be withheld. The therapy of hypoparathyroidism has been discussed.

The causes of *all* *alosis* may be divided into those in which respiratory loss of carbon dioxide is excessive, those in which alkali intake is excessive, and those in which loss of extracellular hydrogen ions is excessive. In the last category are included excessive loss of gastric acid and excessive loss of hydrogen ions from the extracellular fluid to the intracellular fluid and to the urine.

Hyperventilation is not infrequently a manifestation of psychoneurosis. With a sudden increase in respiratory rate serum carbonic acid is lowered by loss of carbon dioxide in the lungs; the serum pH is elevated and tetany may follow. The condition is readily remedied by having the patient breathe into a paper bag or inducing him to decrease his respiratory rate. In this form of alkalosis alone serum bicarbonate is normal or low.

Excessive intake of alkali and excessive loss of gastric acid may produce alkalosis and tetany. The diagnosis, which should be clear if a history is obtainable, is supported by the finding of an elevated serum bicarbonate and an alkaline urine. The tetany should respond to measures designed to prevent vomiting and of course to cessation of alkali therapy. Excessive secretion of adrenal cortical hormones (as in primary aldosteronism) or treatment with analogous steroids may lead to loss of extracellular fluid, hydrogen ions both to the urine and to the cells. A concomitant depletion of potassium, which is essential for the loss to cells, aggravates the urinary loss as well. The tetany, which results, responds to the alleviation of the hormonal excess and the repletion of body potassium.

### PSEUDOHYPOPARATHYROIDISM

**Definition.** Pseudohypoparathyroidism is a condition in which the chemical abnormalities of hypoparathyroidism exist in the presence of normal or hyperplastic parathyroid glands and in the absence of renal glomerular insufficiency. It is generally part of a syndrome involving developmental changes of bone. An essential feature in its recognition is the demonstration of non responsiveness to parathyroid extract.

**Etiology.** Nothing is known of the etiology of pseudohypoparathyroidism. Resistance to parathyroid extract is found but circulating antibodies or precipitins have not been demonstrated. Certain elements of the disorder suggest a relationship to the hereditary disorders achondroplasia and myositis ossificans progressiva. Since the characteristic epiphyseal changes and metaplastic bone growth are found in these conditions in the absence of serum chemical abnormalities, it appears that the anatomical and hormonal features are related genetically but are not interdependent.

**Incidence.** Pseudohypoparathyroidism is a very rare disease, the incidence of which cannot be accurately evaluated. Since it was first described in 1942, a few new cases have been reported and a few cases formerly classified as idiopathic hypoparathyroidism have been reclassified under this heading.

**Morbid Anatomy.** The essential features of morbid anatomy are the presence of normal or hyperplastic parathyroid glands, the short stature and round face found in most patients, the shortened metacarpals and metatarsals and ossifications in skin and tendon.

**Pathological Physiology and Chemistry.** The sequence of chemical events in this condition is the same as that in idiopathic or postoperative hypoparathyroidism and the cardinal biochemical signs are the same with the significant difference that parathyroid extract given intravenously in a dose which produces marked hyperphosphaturia in the former conditions produces little or no change in urine phosphate in this one. As might be anticipated, it fails also to lower the serum phosphorus or to raise the serum calcium.

**Symptoms.** The symptoms and signs of pseudohypoparathyroidism include all those of idiopathic hypoparathyroidism with the possible exceptions of papilledema and associated moniliasis. In addition, patients characteristically show short stature and roundness of the face.

In most cases certain of the metacarpal and metatarsal bones are abnormally shortened as a result of early epiphyseal union. The corresponding shortness of fingers and toes is readily apparent. In many there are found metaplastic islands of true bone in skin and connective tissues; these features have suggested a relationship with achondroplasia and myositis ossificans progressiva. In Brown's case, mother and daughter both had stigmata of achondro-

plasia as well as multiple exostoses and the daughter had in addition pseudohypoparathyroidism. Mental deficiency is present in most cases and does not depend upon a history of convulsions.

**Diagnosis** This is established by finding the serum chemical abnormalities of hypoparathyroidism without those of glomerular insufficiency and by demonstrating less than a twofold increase in urinary phosphorus excretion following administration of 200 units of active parathyroid extract intravenously (The activity of the extract should be checked simultaneously in a normal subject). The features discussed above may obviously be of considerable help in diagnosis. The demonstration of parathyroid tissue by biopsy establishes the diagnosis unequivocally.

**Treatment** The treatment is that of hypoparathyroidism in general: larger doses of

AT 10 may be required than are needed in idiopathic hypoparathyroidism.

## DISEASES OF THE PITUITARY GLAND

## The Hormones of the Anterior Lobe

The hormones of the anterior lobe are proteins or polypeptides. Of these six are now considered to be chemical and biological entities. They have been purified to varying degrees and repair specific anterior lobe defects in hypophysectomized animals. These six are the growth hormone or somatotrophin, prolactin or the lactogenic hormone, the follicle stimulating hormone, the luteinizing or interstitial cell stimulating hormone, thyrotrophin and adrenocorticotrophin or corticotrophin.

The materials now available, however homogenous, however pure, however well characterized, should be considered representatives of these hormones rather than the actual secretions themselves. Detection of biological activity in the blood stream and in the urine is often difficult and satisfactory assay is only now being approximated in a few instances. Precise comparisons between the properties of extracted agents and those predicted or inferred from physiological study and from the study of disease in animals and man are still required. Extracted material may well represent associations between a true hormone and the proteins of the cells that make it and may represent this association in various steps of the manufacture of this hormone. On occasion even artifacts may appear. Nevertheless the current accomplishments fathered by advances in protein chemistry are great indeed and several available agents may approximate closely the secretions as delivered to the blood stream.

**The Growth Hormone or Somatotrophin**  
The existence of this hormone was inferred from the excesses and deficiencies of somatic growth in man as exemplified by gigantism and acromegaly on the one hand and by dwarfism on the other. Subsequently dwarfism was produced by hypophysectomy in dogs (Aschner 1910) and in frogs and rats (Smith 1916-1926). The hormone is defined by its capacity to repair this defect in general body growth following hypophysectomy and to carry this growth

to characteristic excess when given in large amounts.

Since the first effective pituitary extracts of Evans and Long (1921) great progress has been made in describing the composition of active material but much of this progress is recent and a matter still for vigorous discussion. A relatively homogeneous protein by electrophoretic diffusion and solubility tests was extracted from beef pituitaries by Li, Evans and Simpson (1944-1945) and a crystalline preparation was obtained in greater abundance from the same source by Wilhelm, Fishman and Russell (1948). Active agents of high purity have now been obtained from fish, sheep, horse, pig, monkey and human pituitaries. Li (1957) has reported molecular weights of 46,000 for the bovine agent, 25,400 for that of the monkey and 27,100 for that of man. He considers the first of these to be a branched polypeptide chain of 396 amino acid residues and those of monkey and of man to be single polypeptide chains with 25,400 and 27,100 residues respectively. Postulates as to certain details of structure have been made. Products obtained by other methods may well differ and those from other species would be expected to. Some nuclear structure common to these diverse molecules may account for the correspondence among them in physiological effect.

Important species differences in the growth response to principles from a given animal source are now appreciated and may well be critical for work in man. The hypophysectomized rat, which has for years provided the governing assay is sensitive to active products from all mammalian species thus far studied. Preparations from fish pituitaries (hake pollack) however exert no effect. The hypophysectomized monkey will not respond to the bovine or pig growth hormones but monkey pituitary extracts induce nitrogen retention (Knobil, Wolf, Greep and Wilhelm, 1957) and repair of the atrophied costal cartilage has been described. Nitrogen retention in patients with pituitary defects has now been induced by monkey and human proteins prepared by Rabin and by Li (1957).

Beck *et al* Henneman *et al* Bergenstal) Forthcoming details should provide a better account of the properties of growth hormone in man than the hitherto irregular and often uncertain results given by the use of bovine material

The influences of somatotrophin upon the organism are relatively well generalized and are expressed by growth and the immediate metabolic concomitants and consequences of the growth process and by a number of other chemical events not so surely related to growth The defects in the thyroid adrenal cortex and gonads that follow hypophysectomy are repaired incompletely or not at all these structures requiring specific trophic hormones for full restitution of function All influences of the growth hormone on these target organs however are not excluded and come up for consideration from time to time Except for these tissues the effects of somatotrophin on the animal dwarfed by hypophysectomy are fairly uniform Skin musculature viscera and the cardiovascular system respond together Even when gigantism overgrowth is induced as in the hypophysectomized or normal rat this harmony largely prevails although excrescences of cartilage bone and the fibrous elements of the skin mark points of special sensitivity to the growth hormone Neoplasia may be induced in normal rats lymphosarcomas arising especially about the tracheobronchial tree and tumors of the adrenal medulla are conspicuous (Moon *et al* 1950) There is little or no established influence of the growth hormone on the brain

There are complex interrelations between the effects of somatotrophin and those of other agents on several growth processes Insulin with its own anabolic influence is a necessary co factor for the general growth response thyroid secretion is necessary for optimal response 11 Oxygenated steroids from the adrenal cortex oppose somatotrophin when present in excess The growth hormone is essential for proliferation of the mammary tree serving in synergism with prolactin and with adrenal and gonadal steroids

Somatotrophin or some companion still not disassociated by the chemists exerts profound influences upon carbohydrate metabolism which have been much studied but which are still imperfectly understood Several of these influences are exerted by preparations comprised chiefly or entirely of the growth hormone The physiological mechanisms involved are complex and

often a subject of disagreement The reviews of Bennet and Evans in Pincus and Thimann and Young will serve to introduce the reader to details Roughly put the animal lacking a hypophysis is exquisitely sensitive to insulin cannot maintain its glycogen stores during fasting and does not show the usual evolution of diabetes mellitus after pancreatectomy (Houssay phenomenon) Extracts restore the state prior to hypophysectomy and may furthermore induce an insulin resistant diabetes in the normal animals of some species (dogs for example) followed by islet cell degeneration and a permanent insulin sensitive diabetes enduring after cessation of treatment (Youngs or metahypophysial diabetes) The growth hormone apparently serves to maintain one element of the fasting carbohydrate stores (muscle glycogen glycolytic effect) It is or else closely associated with the diabetogenic agent effective in the normal dog in which it appears to act independent of the adrenal cortex Thus it seems likely that the association of unusual growth and diabetes mellitus in acromegaly may well be due to excesses of a single agent the capacity of the individual pancreas to secrete insulin determining whether diabetes will or will not occur

The adrenal hormone secreted in response to ACTH is likewise diabetogenic in certain species (man and partially depancreatized or force fed rat) and antagonizes the action of insulin These are presumably the experimental analogues of the diabetes mellitus of Cushing's syndrome The precise nature of the interrelationships between the activities of the growth hormone and those of the adrenal steroids on carbohydrate metabolism is obscure and it is not clear whether the liability of patients with hypopituitarism to spontaneous hypoglycemia or their sensitivity to insulin is due chiefly to the lack of the one or of the other or of both

The amounts of the growth hormone circulating in the human system can be assessed now only by its effects No workable biological assay of the agent in body fluids is available although its presence has been detected in the plasma of acromegalics At the moment therefore estimates depend on a congeries of clinical and intrinsically nonspecific laboratory techniques Though a good deal can be accomplished by sophisticated use of what we have better methods are badly needed

**Prolactin (Lactogenic Hormone, Luteotrophin)** This agent induces lactation in the suitably prepared breast and is apparently

necessary for the growth and development of the mammary apparatus. Highly purified proteins obtained by A. White and by Li *et al.* from beef and sheep pituitaries (1942) were much alike. Li has subsequently reported a molecular weight of 33,000 for sheep prolactin with an assignment of amino acid composition. It contains no carbohydrate. In the hypophysectomized rat, complete replication of the architecture of the breast in pregnancy together with lactation depends upon the properly balanced action of prolactin, somatotrophin, estrogen, progesterone, and adrenocorticotrophin (Lyons, 1943, 1955). Such complex synergisms may be expected wherever prolactin is concerned. Lactation, first demonstrated with crude extracts in rabbits (Stricker and Grueter, 1928), has now been induced in women and men by Huggins and Dao (1954). Influence on breast growth in the human is hard to evaluate. Regression of some breast tumors after hypophysectomy may be due to withdrawal of prolactin support. Purified prolactin evokes secretion of progesterone from the corpus luteum of the rat by the action of the luteinizing hormone on the prepared ovary (Astwood). So far, this function, leading to the use of the name "luteotrophin," has not been identified in other species but may exist there. Assay is now usually determined by the response of the crop gland of the pigeon (Riddle and Bates, 1932, 1933). Active material so measured is present in human urine and, according to Segaloff, shows increments during the menstrual cycle, suggesting participation in the control of the human ovary. Even broader functions may exist as certain somatotrophic influences on liver and cartilage have been shown in other species.

**The Follicle Stimulating Hormone (FSH)**  
The best products from the chemical standpoint indicate a glycoprotein stimulating and necessary for the growth of the ovarian follicle but requiring a co-factor provided by the luteinizing hormone (LH) at least for estrogen secretion and for ovulation. In the male, spermatogenesis is facilitated although androgens alone arising in response to LH may suffice to support spermatogenesis in some species. In all probability, there is some systematic scheme whereby FSH and androgens cooperate in the control of the seminiferous epithelium with experimental conditions and species variations dramatizing first one aspect and then the other but leaving the overall pattern incoherent and inconsistent to us for the moment.

Normal human urine contains a gonadotrophin or gonadotrophins which may be increased to as much as tenfold or more by removal of the gonads or by the normal involution of the ovaries at the menopause. Unfortunately, this material has not been sufficiently purified to permit precise chemical definition. It has follicular growth provoking properties and excites estrogen secretion and, if the analogy with anterior lobe extracts holds, may be dual in composition. Unlike chorionic gonadotrophin, abundantly secreted by the human placenta during pregnancy, it requires no pituitary co-factor for its influence on the ovaries acting in hypophysectomized animals. Spermatogenesis and androgen production are facilitated by suitable doses in the male. The material may be assayed with fair efficiency either by its effects on the ovaries or by its indirect effects on the uteri of immature rats or mice. More recently, the response of the ventral prostate of the rat has served to define the interstitial cell stimulating properties. The results are of great value in determining whether the pituitary body or the gonads are primarily responsible for gonadal deficiency. High values bespeak primary gonadal defect; low values indicate pituitary defect if repeatedly obtained. Normal values are ambiguous. The administration of estrogens (or androgens in sufficient doses) inhibits the secretion of these materials by the anterior lobe.

The administration of foreign gonadotrophins to man for purposes of exciting the ovarian follicles to grow and to secrete estrogens has been disappointing. The difficulties may lie in the products, in antihormone formation, in imperfect knowledge of the character of the defect in the subject and in failures to imitate nature's delicate synergism between FSH and LH. There is every reason to believe that all factors are involved.

**The Luteinizing Hormone (LH) or Interstitial Cell Stimulating Hormone (ICSH)**  
This is a glycoprotein. Purified (or pure) agents from swine (Chow *et al.*, 1942) and sheep (Li *et al.*, 1940-42) differ chemically. This hormone is a synergist and a companion hormone to FSH. It may cooperate with FSH in maturing the ovarian follicle and is essential to ovulation and formation of the corpus luteum. It is now usually held responsible in great part for estrogen secretion. In rats, at least, continued secretory activity of the formed corpus luteum is attributed to luteotrophin rather than to LH. The trophic influence of LH on the interstitial cells of the ovaries of rats

although used for assay has not yet acquired real physiological meaning. Luteinizing hormone is however a powerful stimulant of androgen production by the interstitial cells of the testes in all species studied. The gonadotrophic material in the urine of normal and castrate humans has LH like propensities despite the common practice of designating only the FSH like properties. Assays are discussed under FSH. Luteinizing hormone of animal pituitary origin has not been successfully given to man although the somewhat similar human chorionic gonadotrophin is quite potent.

**The Thyrotrophic Hormone (TSH)** This agent is defined by its capacity to repair the atrophy and secretory defects of the thyroid gland that follow hypophysectomy. Sufficient doses induce hypertrophy and hyperplasia of the cellular elements of the thyroid and the secretory excess of hyperthyroidism. Discharge of thyroxin from the follicles is accelerated, a proteolytic enzyme serving to release the hormone from the intrafollicular protein thyroglobulin. The manufacture of new hormone to replace that lost is accelerated. Extraction of iodide from the blood stream is sharply increased.

Thyrotrophin itself has not thus far been isolated or sufficiently characterized. A molecular weight of 10 000 has been estimated although it may well be less (Ciereszko 1945; Hays and Steelman 1955). It appears to be a glycoprotein. Pituitary extracts chiefly thyrotrophin exert effects in the absence of the thyroid. Exophthalmos is a notable example; its evolution depends in part upon the deposition of hydrophilic mucopolysaccharides in the ground substance of the connective tissue of the orbit. The striated musculature including that of the orbit may suffer such infiltrates. Movement of fat from body depots into the liver and elsewhere including the striated musculature has been noted. How many of these influences are due to thyrotrophin and how many to associated agents is uncertain. Dobyns and Steelman (1953) suggest an "exophthalmos inducing factor" separate from thyrotrophin measuring exophthalmos by the response in the fish *Fundulus*.

Assays for thyrotrophin in human body fluids have permitted detection of activity in both blood and urine but have not advanced to the point of simplicity and reliability. Among the most interesting techniques is that of D'Angelo (1951). Use of the tadpole in which metamorphosis is suspended by starvation permits detection of both thyrotrophin and thyroid hormone

in the same serum. Advancement of metamorphosis occurs with either agent but the preponderance of thyrotrophin is indicated by hypertrophy of the thyroid epithelium. Thus determined thyrotrophin has been detected in normal serum. The thyrotrophic theory of Graves disease has not been supported by the finding of excess thyrotrophin in the serum. In progressive exophthalmos high values have been found but agreement on the point has hardly been reached. In acromegaly elevated values may appear but not consistently related to the occurrence of hyperthyroidism.

Thyrotrophin largely of beef origin will provoke hyperthyroidism in man. Increments in protein bound iodine (including the butanol extractable moiety chiefly thyroxin) and increased uptakes of iodine measured by radioactive iodine are induced. The process could not be sustained for long periods by the older extracts, antibodies rising in the host to terminate the influence of the foreign hormone. More recently thyrotrophin has been injected to assess the reactivity of the thyroid in hypothyroidism. A response indicated that the thyroid itself is not at fault and suggests hypopituitarism. Standardization of this procedure has hardly been achieved and the wisdom of general use of our still impure products is questionable to this writer (For details of proposed methods see Williams text 1955).

**Adrenocorticotrophin (ACTH, Corticotrophin, corticotropin)\*** This hormone exerts a trophic influence upon the adrenal cortex, repairing its morphological and secretory deficiencies in the hypophysectomized animal and inducing hyperplasia and hypersecretion in the normal animal. The original proteins isolated by Sayers and his colleagues (1943) were estimated to have molecular weights approaching 20 000 but following the work of Astwood and his associates (1951-1952) it became apparent that degradation to much smaller polypeptide moieties results in no loss of biological activity. Shepherd and Bell have obtained a virtually homogeneous polypeptide from hog pituitary ( $\beta$ -corticotrophin) which has a sequence of 39 amino acids nearly identical to the sequence in  $\alpha$ -corticotrophin isolated from sheep pituitary by Li and his group (1955). The estimated molecular weight is 4000 to 5000. By means of pepsin as many as 11 to 15 amino acid residues may be split off from the C terminal (not from the N terminal) end with preservation of activity so that the essential

hormone may be a still simpler substance

A controversy exists as to the biological nature of adrenocorticotrophin i.e. whether it is one substance or several. For example the older ACTH protein enhanced adrenal weight to a greater degree than it did steroidogenesis whereas the newer ACTH peptide produced reverse effects. Furthermore Reinhardt, Geschwind and Li (1951) and Young and Stack Dunne (1951) have isolated pituitary fractions with different ratios of adrenal weight augmenting to steroidogenic potency and have suggested the possibility that there are two corticotrophins with these separate activities. It is difficult to state with certainty at this time whether the adrenal weight augmenting material is a corticotrophin or whether it is related more closely to somatotrophin (Young). Its relation to the purified polypeptides described above is unknown. A third substance melanocyte stimulating hormone or MSH (analogous to the melanophore-expanding principle found in the intermediate lobe of the amphibian pituitary) has aroused interest as a result of earlier difficulties in separating pigmentary and adrenocorticotrophic effects of various pituitary fractions administered to man (Lerner 1955) and also in view of the demonstration by Sulman (1956) and others of elevated blood concentrations of MSH in clinical situations characterized by demonstrably high plasma concentrations of ACTH (e.g. Addison's disease). It now seems likely that MSH is truly a distinct substance. Thung and Li have achieved electrophoretic separation of MSH from ACTH and Li and Harris and Roos have isolated a substance with a sequence of 18 amino acids and a minimum molecular weight of about 2000. Corticotrophin and MSH have a short amino acid sequence in common which may explain in part why there is feeble but definite MSH activity in pure ACTH.

The cellular origin of ACTH or of the ACTH complex in the pituitary gland is not definitely known. Much circumstantial evidence favors the basophil. For example Kulby, Bennett and Sprague (1957) found hyaline and other changes exclusively in basophils of patients treated with corticotrophin (or cortisone) and Marshall (1951) provided immunological evidence that ACTH antihormones (antisera) localized only in basophilic cells.

The mechanisms regulating ACTH release from the pituitary are complex and controversial. At least two seem well established. Corticotrophin release rate is inversely related to the level of circulating adrenal

cortical glucocorticoid (Sayers 1950). Adrenal cortical extract brings about adrenal atrophy mediated through inhibition of endogenous ACTH (Ingle 1938). Conversely patients with Addison's disease who have reduced or absent blood steroid levels exhibit increased amounts of ACTH in the plasma (Taylor *et al.* 1949, Paris *et al.* 1954 and others). The second or neurohumoral mechanism has been extensively studied by Harris and his group, Hume, Porter, McCann, Munson and Briggs and Guillemin (1950-1958). In brief the organism is presumed to react to a stimulus by activation of hypothalamic centers which in turn may secrete a neurohumor into the hypophyseal venous portal system. This material is carried to the adenohypophysis where it induces release of corticotrophin. The nature of the postulated neurohumor is unknown but there is evidence suggesting that it is not histamine, serotonin, vasopressin or epinephrine (reviewed by Jailer and Christy 1957).

The physiological role of corticotrophin is implicit in the foregoing discussion. Its function is to maintain the morphological and secretory integrity of the adrenal cortex. A wide variety of noxious stimuli are associated in man with increased output of adrenal cortical steroids and by inference with an increased rate of endogenous ACTH release. These stimuli include acute and chronic illnesses of several types (Perkoff 1954): typhoid vaccine (Conn 1954), insulin hypoglycemia (Migeon 1953), stressful interviews and subacute emotional disturbances. Direct assay for adrenocorticotrophin is difficult but no intrinsic defect of corticotrophin secretion or of the pituitary-adrenal system has been conclusively shown in those systemic diseases ameliorated by ACTH or cortisone. The relation between this hormonally mediated improvement and Selye's concept of an etiological or pathogenetic maladaptation to nonspecific stress remains controversial.

In man administration of ACTH causes hyperemia and adrenal enlargement (especially of the zona fasciculata). Studies of adrenal vein blood have shown that the chief secretory products of the ACTH-stimulated adrenal gland of man are hydrocortisone (compound F of Kendall) and corticosterone (compound B) (Bush and Sandberg, Romanoff *et al.* 1953). Only minor increments in aldosterone secretion have been produced by ACTH administration (Gordon). Haynes (1957) has shown that increased steroidogenesis is a result of increased synthesis and not of augmented

release. Clinical measurement of plasma and urinary 17 hydroxycorticosteroid levels shows elevations during and for a few hours following ACTH administration (Nelson Samuels *et al* 1952-1955 and others). Detailed identification of urinary steroids following ACTH has shown increases in 11 desoxy and 11-oxy 17 ketosteroids the latter being end products of hydrocortisone metabolism (Gallagher *et al* 1955) increased amounts of C-21 metabolites of hydrocortisone (*e.g.* tetrahydrocortisone cortol) and the emergence of 11 desoxy hydrocortisone (compound S of Reichstein) (Touchstone 1955-1956).

The physiological effects of ACTH in man are in essence those produced by cortisone or hydrocortisone administration—an expected consequence of the finding that hydrocortisone is the steroid the production of which is most augmented by corticotrophin. In theory minor differences between ACTH and hydrocortisone effects might be explained by the ACTH induced increment in corticosterone a fairly potent mineralocorticoid. Certainly there are no differences compelling the use of corticotrophin which must be injected when virtually the same effects can be achieved with steroids which may be given by mouth. The well known effects of ACTH and hydrocortisone upon carbohydrate protein and sodium metabolism upon muscle function and the central nervous system and their androgenic effects do not provide hints as to how these hormones ameliorate disease. The inhibitory influence exerted upon tissue response to injury (Ragan *et al* 1950) and upon antibody formation (Bjørneboe *et al* 1951) may by analogy furnish a basis for understanding the beneficial effects upon inflammatory and hypersensitivity disorders.

ACTH is also capable of producing all the side effects of the adrenal steroids. Prolonged administration is associated with the stigmata of Cushing's syndrome (hypertension osteoporosis occasionally glycosuria psychosis and so forth).

Although as stated above there is little reason to administer ACTH therapeutically over a prolonged period when steroids will do as well corticotrophin has found wide use in preventing symptoms of hypocorticism which result from long term steroid therapy with its accompanying adrenal atrophy. It is probable that ACTH administration will accelerate return of adrenal weight and of adrenal response to ACTH toward normal. However there has never been rigorous experimental proof that ACTH therapy can accelerate return to nor-

mal of endogenous pituitary response to stress. It can therefore be argued that gradual steroid withdrawal may allow as rapid a restoration of a normal pituitary-adrenal relationship as does ACTH therapy for a period of a few days.

**Chorionic Gonadotrophin.** The placenta of several species constitute temporary but important organs of internal secretion with gonadotrophic properties so nearly like those of the anterior lobe that brief if incomplete notation must be given here. Chorionic gonadotrophin is apparently a glycoprotein arising from the human placenta and excreted in the urine. It gives the classic Aschheim Zondek test for pregnancy by its gonadotrophic properties in immature mice and the Friedman test by its capacity to evoke ovulation in the rabbit in heat (it is others). It does not produce follicular excretion in large amounts by men with testicular tumors (chorionepithelioma) and growth in the ovary of the hypophysectomized rodent differing thereby from pituitary and castrate urine factors. It is a powerful agent in protracting the life and function of the normal corpus luteum in women and in exciting androgen secretion in men with responsive testes. Its real usefulness in correcting disorders of the menstrual cycle is uncertain.

**Pregnant Mare's Serum Gonadotrophin.** This is a protein with both follicle stimulating and luteinizing properties. It produces antihormones readily in man in contrast to human chorionic gonadotrophin. Its usefulness and effectiveness in man is a matter of disagreement.

## Hyperpituitarism

### ACROMEGALY AND GIGANTISM

**Definitions.** Acromegaly is a chronic disease characterized essentially by the progressive and systematic overgrowth of many tissues in response to intense and long sustained stimulation by the growth hormone of the pituitary body. Other hormones may well cause certain expressions of the disorder although they are not now known to promote the characteristic overgrowth. The name "acromegaly" (Marie 1886) designates the striking and presenting enlargement of the acral or terminal portions of the body the hands feet and certain elements of the face and head. Gigantism appears not surely a clinical entity. Some half

FIG 75 Roentgenogram of skull of an acromegalic with verified eosinophilic adenoma of the hypophysis. Note the ballooned sella turcica, thick skull, large frontal sinus and large mandible.

or more of the recorded giants are acromegalic. Here the youthful epiphyseal cartilages of the long bones proliferate in response to the excess of growth hormone, a process favored by any influence such as gonadal insufficiency which delays their ossification. A serious re-examination of etiology is required in those giants in whom no vestige of acromegalization ever occurs. Constitutional factors apart from endocrine influences may be important, forming a counterpart to the group of primordial dwarfs at the other end of the scale of size.

**Etiology.** Acromegaly and that form of gigantism properly associated with it are due to hypersecretion of the growth hormone from abundant neoplastic or hyperplastic cells of the anterior lobe of the pituitary body. The excess of growth hormone provoking the dominant expressions of the disorder may be considered coming from these cells. Since Bender's observation (1900) eosinophils or alpha cells have been held responsible, although recently (Russfield 1956) "amphophiles" have been spoken of—a suggestion of still uncertain fate. Adenomas are most frequently described in autopsy or surgical material, although diffuse hyperplasia may occur. Over one half of the patients with acromegaly trace the onset to the third decade. No useful theory accounting for this timing has appeared. The sexes are affected equally, although gigantism affects males chiefly. Only 40 per cent of acromegalics give a his-

tory of similarly affected family members, although in 20 per cent some note is made of large relatives (Davidoff 1926). A hereditary predisposition to diabetes mellitus as a complication seems clearer (Coggeshall and Root 1940).

**The Pituitary Body and Its Environs.** The pituitary is usually large and the proliferative process considered adenomatous, although hyperplasia occurs on occasion. Although cellular aberrations are common with multinucleate cells and amitotic division and the term carcinoma has been applied in some instances, metastases are rare. Spread is largely by direct extension of the main tumor mass. Eosinophils (acidophils, alpha cells) typically dominate the cellular population. Granulation, however, may be sparse and faint staining with the periodic acid-Schiff reagent may be seen in contrast to the lack of such staining in the typical eosinophil. Transition forms between eosinophil and chromophobe tumors have long been known and should be given a somewhat different meaning than that which the rather casual statements of the past implied. Electron microscopy (Reichert 1954) shows many granules in chromophobe cells of normal human pituitaries not easily detected by stains. A number of active tumors in man show little granulation. Some of these have caused relatively indistinct forms of acromegaly; others now are known to induce a syndrome with persistent lactation and amenorrhea, signs which merge into those associated with acromegaly; others still may be associated with Cushing's syndrome. It is of especial interest in this connection that the highly active pituitary tumors of mice studied by Furth (1953-1958) often show little of the familiar granulation. There still remain then some engaging mysteries in the relationships between cytological detail and the functional expressions of pituitary tumors.

The growth of the tumor is typically slow and progressive. The sella turcica is visibly distended in the majority of instances and assumes a ballooned appearance from pressure within its confines (Fig 75). The average adult sella turcica measured by roentgenogram is 5 to 8 mm in depth and 9 to 10 mm in length. Upper normal limits are variously given as 10 to 12 and 12 to 16 mm, respectively.

These limits are usually but not necessarily substantially exceeded. The floor of the sella is commonly depressed and the sphenoid cells may even be invaded. At first the dorsum sellae is displaced back

wards Together with the clinoid processes it may eventually be eroded and destroyed The diaphragma sellae is forced upwards and may be ruptured Pressure is thus exerted upon the overlying optic chiasm and neighboring portions of the optic system A number of other cerebral areas come to express damage in their own particular ways

The tumor may appear stationary for years accommodations to existing pressure may take place and secretory activity may decline into relative quiescence Thus a stage of arrest which may last for almost any length of time supervenes Irregularly phasic activity may recur from time to time

**Symptoms, Signs and Course** The outward appearance of the well advanced acromegalic conforms as a rule to a single easily recognized type There is thickening

and coarsening of the features notably of the lips and nose with accentuation of the normal eminences of the brow nose and lower jaw Mandibular prognathism is characteristic The hands and feet are large the thoracic cage increased in size the back stooped These deformities are exaggerations of familiar normal variations of man The continued growth of connective tissue and bone traverses the path from the not remarkable through the merely peculiar to the obviously deformed so slowly and by such imperceptible gradations that the early phases escape identification by the expert Even the later phases may seem right and proper though unusual to the patient and his family In gigantism accelerated longitudinal growth commonly appears in late boyhood and lasts longer than usual The typical stigmata of acromegaly are superimposed in due time

FIG 76 Acromegaly A and B Note the large and elongated head large hand nose ears and lips There is also prognathism and slightly increased interdental spaces C Note the coarse features D Large blunt thumb (R H Williams Textbook of Endocrinology)

As this massive appearance emerges a contrasting enfeeblement afflicts the victim. The disabilities are numerous. Muscular weakness is eventually the rule although accounts of considerable early vigor are given. Amenorrhea or impotence commonly occurs. Excessive sweating is common. Diabetes mellitus supervenes in some 15 per cent or more. The hypertrophied and distended extremities may be painfully uncomfortable, the affected joints of the extremities and spine stiff and painful. Pain of neuritic character may occur. The expansion of the tumor against the bony and ligamentous investments of the sella produces headaches which may be referred to the temporal area or elsewhere and which may be intense and continuous enough to disturb sleep. On the other hand the pain may be transient or even insignificant. As a result of pressure visual difficulties progressing to blindness are common. Most typically the focus of pressure bears anteriorly impairing conduction in the decussating nasal nerve elements yielding bitemporal hemianopsia with initial upper quadrant defects. Color vision is affected before form vision. Many varieties of visual defects occur however with blindness only in the affected eye and homonymous hemianopsia among them. Choked disk is rare. As the growth extends the brain suffers from direct encroachment of the tumor from displacement and from obstruction to the ventricular systems. *Drowsiness, polydipsia and polyuria* may signify injury to the hypothalamus. Usually after years of illness death comes from the brain tumor from cardiac failure from diabetes intercurrent disease or ultimate hypopituitarism. The course is subject to great variations and long or even permanent remissions can occur leaving the structural changes to mark the hormonal influences of the past.

**Hormonal Influences on Structure and Function.** The greater part of the general somatic expressions of the disease are due to excessive secretion of the growth hormone of the pituitary body. Chondrogenesis is stimulated with manifold consequences. Increased proliferation of youthful epiphyseal cartilage elongates bones. Gonadal defect secondary to the pituitary disorder diminishes androgens and estrogens. Since these sex hormones tend to favor the ossification of the cartilages of the long bones continued growth is favored by their lack. In the adult residual cartilage responds to stimulation. The costal cartilages hypertrophy thus contributing decisively to the

*enlargement of the thorax* ■ special form of arthritis follows proliferation of the deeper layers of joint cartilage. Growth of nasal and ear cartilages contributes to the acromegalization of the face and hypertrophy of the laryngeal cartilages makes for a *deep and husky voice*. Osteogenesis succeeds chondrogenesis in gigantic overgrowth. Osteogenesis from periosteum is greatly accelerated but so accompanied by resorptive processes that systematic alteration in shape is accomplished and the enlarged bones may come to be rarified rather than condensed. Although the skull may be thickened generally with expansion of the diploic portion the frontal bone especially grows with protrusion of the supraciliary ridges and extraordinary excavation of the frontal sinuses beneath. The ramus of the mandible extends and the angle is blunted thus advancing the lower jaw in the classic *mandibular prognathism*. Heaping of new alveolar bone separates the teeth. The bones of the hands and feet may be enlarged with *tufting of the terminal phalanges*. The vertebrae may come to be virtually enclosed by shells of new bone. Points of ligamentous and muscular insertions generally are accentuated by ossification within or about the attached structures the ligamentous apparatus of the spine especially becoming affected.

Despite this extensive growth of bone the actual enlargement of the body members is commonly due chiefly to proliferation of the soft parts and in certain acromegals it may be difficult to prove exceptional bone growth at all. The true skin thickens and considerable *hypertrichosis* is common. The sweat gland mass has been reported increased. Connective tissue in the skin and in the subcutaneous and submucosal regions grows in excess giving the *large broad hands and feet* and the full lips and nose increasing the flaccid cutaneous structures about the eyes and producing the thickened corrugated "bull-dog" scalp. Hypertrophy of the soft parts about joints and fiber proliferation here and in the cartilage contribute to the arthritis. The tongue is often large with great hypertrophy of the papillae. Internal structures share the growth of these external and supporting tissues. The liver may be twice or more the normal size and the lungs, spleen, pancreas and intestines enlarged. Graffius account based on a model reconstruction shows that renal growth depends on hypertrophy of individual nephrons. The heart may weigh as much as 1 kilogram more than three times normal with varying

growth and fragmentation of individual muscle fibers. It is uncertain whether circulatory demand is sufficient to account for cardiac growth by work hypertrophy and a primary influence of the growth hormone on the cardiac musculature may be involved. Skeletal muscle may respond for a time but progressive hypertrophy to a striking degree is not conspicuous. Asboe Hansen has noted deposition of metachromatic material in the musculature similar to that induced by thyrotrophin. The brain does not itself grow although perineurium about peripheral nerves does proliferate and certain ganglia have been reported enlarged.

Experimental research leaves little doubt that the associated growth of skeleton, connective tissue and viscera is due to the secretion of abnormal amounts of a single growth hormone. Similarly thymic hypertrophy known in acromegaly since Fritzsche and Klebs (1884) appears due to excesses of the growth hormone. The frequent diabetes may well be due to the growth hormone. This diabetes is variable in intensity may or may not require large amounts of insulin for control and may undergo spontaneous remissions. Pituitary extracts rich in the growth factor exert influences on carbohydrate metabolism opposed to those of insulin and create a strain upon the islet mechanism. Randle (1954) has found an excess of a factor in the plasma of acromegals which enhances the uptake of glucose by the diaphragm of the rat in the manner of insulin. The capacity of the patient's pancreas to secrete insulin would determine whether or not diabetes will ensue. Ultimate degeneration of the islets analogous to that in dogs or cats (Youngs or metahypophyseal diabetes) may conceivably occur but has not been established at autopsy.

Several other characteristics of the disease are less clearly due to excesses of the growth hormone or cannot be so accounted for at all. The basal metabolism is commonly increased to plus 15 or 25 or more. This contributes to the excessive sweating but is probably not a sole and necessary cause. Exophthalmos may occur. These features together with tachycardia and goiter may combine strongly to suggest complicating Graves disease directing treatment toward the thyroid and suggesting excessive thyrotrophin as a factor in pathogenesis. Though Graves disease certainly is present at times the signs and symptoms suggesting it may often be misleading. Dissociation of these signs and symptoms is com-

mon. The goiters are often large and of a nodular colloid type and thyroidectomy or the use of antithyroid drugs may prove disappointing. Although assays for thyrotrophin have been found elevated no correlation exists between this elevation and expressions of hyperthyroidism.

Vascular hypertension may occur in cases of long standing and may in part be due to sclerosis of small vessels although the matter has not been carefully studied and other factors may enter in.

The participation of ACTH in the process of acromegaly is uncertain. Although moderate overgrowth of the adrenal cortex is common, studies of urinary 17 ketosteroids have not given high results and the typical clinical expressions of Cushing's syndrome are rarely intermixed with acromegalization. The hypertrichosis of acromegaly may be due to the growth hormone itself. Since adrenal hormones appear to be antagonists to the anabolic effects of the growth hormone on protein metabolism, a case could be made out for their reactive and compensatory hypersecretion. Both plasma corticotrophin and urinary corticoids have been found elevated on occasion.

The excessive lactation in acromegalic women may or may not have to do with prolactin. The growth hormone itself may contribute.

The gonadal defects in acromegaly and gigantism are presumably due to secondary damage to gonadotrophic elements of the pituitary itself either by pressure from the tumor or by involution in some subtle consequence of eosinophil proliferation. No direct damaging effects of the growth hormone on the gonads are known with the better extracts. The occasional complicating myxedema may be interpreted along similar lines. Manifest general hypopituitarism may be an end result of exhaustion of the secretory elements and of their destruction by pressure and necrosis but this time honored concept could well stand modern documentation.

**Diagnosis.** A firm grasp of the clinical expressions of acromegaly is usually adequate preparation for recognition of the disorder. The appearance in the advanced stages is pathognomonic but its early recognition may be difficult and in some cases time alone may tell. A documented history of progressive and unusual increases in size is important. Increasing shoe and glove size or the imperfect fit of old rings may be suggestive. Photographic records of changing features are most useful. On occasion the fullness of the lips and tongue the

huskiness of the voice and puffiness about the eyes suggest myxedema but the pallor loss of head and body hair dryness of the skin and depressed heat production characteristic of hypothyroidism are usually absent in acromegaly Paresthesias and pains about the joints and elsewhere may be considered rheumatic or arthritic and the headaches may be wrongly assigned to that vast obscure category of functional headaches including migraine Roentgenograms of the skull usually but by no means always show typical excavation and enlargement of the sella turcica by the time the signs and symptoms cause concern Later perimetric studies of the visual fields may show distortion from pressure first in color fields later in those for form

Measurements of the secretory activity of the adenoma are indirect and imperfect Albright has suggested that increases in serum inorganic phosphorus may serve to indicate excesses of the growth hormone The method has experimental support and may well prove useful The basal metabolic rate may be normal or elevated Diabetic glucose tolerance curves or frank diabetes mellitus usually speak for hyperactivity particularly if accompanied by any notable insulin resistance Serial evaluations of secretory activity x rays of the sella visual studies and neurological examinations are essential for years once the disorder is established for the appraisal of activity of the disease process

**Treatment** In embarking upon treatment it is necessary to judge the size of any existing pituitary adenoma and its rate of growth to estimate the secretory activity at the time and to assess the extent of damage to the visual pathways and the brain

Irradiation of the pituitary body by x rays is preferred More intensive radiation than hitherto used has been recommended by Johnsen (1952) Arrest of the process often occurs as judged by improvement in the visual fields headache and in signs of secretory activity The imperfections of measurements and the exceedingly slow and variable course of the disease itself make evaluation difficult Albright has recommended the use of large doses of diethyl stilbestrol based on the capacity of estrogens in experimental animals to deplete the anterior lobe of eosinophils and to retard growth Depression of serum inorganic phosphorus suggested reduction in growth hormone secretion but the eventual course of the tumors remains uncertain Surgical removal of the adenoma is commonly re-

served for those whose sight is threatened but the current advancements in extirpation and destruction of the hypophysis may well extend the usefulness of these procedures in acromegaly As it stands now all methods may fail and smoldering residual activity may prevail with lingering disability of varying degrees

**Associations of Acromegaly and Other Syndromes** Tumors of the pituitary body inducing acromegaly may be associated with functioning endocrine tumors elsewhere notably with parathyroid and islet cell adenomas of the pancreas (Wermer 1954) the syndrome being called *endocrine adenomatosis* The signs of these disorders should be watched for Chromophobe tumors not inducing hyperpituitarism may be similarly associated (Underdahl *et al* 1953) As noted earlier there is a gradation between granule bearing and non granule bearing tumor cells and cells giving evidence of functional activity may be termed chromophobe Some of these are associated with galactorrhea and amenorrhea (Forbes *et al* 1954) The excretion of urinary gonadotrophins appears reduced Such excessive lactation may appear in acromegaly and there is a reasonable disposition to assign the galactorrhea in both instances to excesses of prolactin The writer is not certain that this has been demonstrated the rather difficult view that there is an inhibitory or destructive action may have to be entertained Similarly tumors which are chromophobe or basophil may be associated with Cushing's syndrome and the issue of excessive secretion of adrenocorticotrophin arises

### Hypopituitarism

The greater part of our clinical information deals with gross destructive lesions of the pituitary body causing numerous defects Isolated impairment of the capacity of the anterior lobe to make one hormone or a group of hormones leaving the remainder of its functions intact is poorly understood for the most part and imper-

fectly documented. In a number of eunuchoids without obvious general defects of pituitary origin urinary assays for gonadotrophin are low and androgen secretion in response to chorionic gonadotrophin may be substantiated. This provides excellent evidence for a relatively isolated pituitary deficiency affecting the entire gonadotrophic complex. Disorders affecting other functions are emerging (Myers *et al* 1953) although uncertainty still exists as to whether or not these are the predominant and prevailing expressions of a gross lesion or whether a single cell line has suffered from some peculiar intrinsic defect.

A form of isolated adrenocorticotrophin deficiency may occur when corticoids are suddenly withdrawn. Fever, prostration and vascular collapse of adrenal insufficiency ensue.

### SIMMONDS DISEASE

(Panhypopituitarism)

**Definition.** Primary chronic hypopituitarism involves defects in several pituitary functions leading usually to more or less general disability. Usage of the term and the criteria for nomenclature are confused for historical reasons.

**History.** Simmonds (1914) described an autopsy on a woman with a history of puerperal sepsis and noted cachexia with loss of weight and atrophy of the skin, loss of pubic hair, amenorrhea and splanchnometria. He attributed the fibrosed pituitary body to septic embolism years before. He adopted the term "pituitary cachexia" emphasizing cachexia as a cardinal feature and subsequently pointed out that similar clinical states followed damage to the anterior lobe from other causes including tumors. Subsequent authors continued this emphasis on cachexia often meaning excessive weight loss although brain surgeons including Cushing for years recognized a related state of geroderma, weakness, loss of pubic hair and sexual defects in the victims of chromophobe adenomas of the pituitary body who might or might not have lost much weight. The emphasis on weight loss has led to the confusion of primary pituitary disease (called Simmonds disease or pituitary cachexia) with anorexia nervosa in certain quarters. Sheehan (1937-1949) has done much to straighten matters out. His major contributions have rested on his detailed description of fresh infarcts in the anterior lobes of women dying from collapse and hemorrhage at childbirth relating these to the ultimate fibrosis described by Simmonds and others in those who survived such injuries and pointing out that cachexia in the sense of weight loss was a relatively infrequent expression of the disease. He suggested postpartum necrosis for the lesions arising at childbirth but retained the name of Simmonds disease for severe hypopituitarism of whatever origin. This work brought the general clinical consequences of postpartum necrosis close to experience with pituitary tumors. Albright's term "panhypopituitarism" has had considerable appeal and is appropriate when used to mean what it says. The writer will use the more noncommittal Simmonds

disease" in Sheehan's sense but the reader must expect a continuing change in terminology as knowledge grows and conventions shift.

**Etiology and Pathology.** Postpartum necrosis of the anterior lobe of the pituitary body is common in women dying from collapse or hemorrhage at childbirth. These infarcts which may be tiny to nearly total have been attributed by Sheehan (1937) to local thrombosis rather than to septic embolism (Simmonds 1914). Strands of viable tissue often survive near the attachment of the stalk or along the capsule. Fibrosis supervenes and years later contracted shreds of anterior lobe tissue may be found in those surviving such obstetric accidents. Direct damage to the pituitary body may occur following head injuries, hemorrhage into its substance being presumably decisive. Granulomas may occur and have been attributed to tuberculosis rarely to syphilis. Fibrosis of a diffuse type distinguishable from the more sharply demarcated scars of infarction has been noted in both sexes since Claude and Gougerot (1908) and is of obscure origin although thought syphilitic by some.

Tumors arising either within or outside the sella may compress and destroy the pituitary body. Of those arising within chromophobe adenomas are the most common. Developing from stem cells of the secretory elements of the anterior lobe they are nonfunctioning save for rare and sparse granulation which may be associated with some degree of activity. Endocrine symptoms are therefore produced largely by impairment of the secretory elements. The sella is ballooned the clinoid process eroded, the visual system encroached upon and the brain invaded much as in the eosinophile adenomas described under Acromegaly.

Craniopharyngiomas (a term not universally accepted) also known as Rathke pouch tumors arise from fragments of the oral epithelium remaining from the primitive invagination. Although intrasellar on rare occasions they are more likely to proliferate from the neighborhood of the upper suprasellar reaches of the stalk. They give symptoms often during childhood in contrast to chromophobe adenomas which typically begin during adult life. Comprised chiefly of oral epithelium often with squamous cells or important dental elements (adamantinoma) these tumors show a strong disposition to necrosis and cyst formation with points of calcification which may be recognized on roentgenograms. The sella is likely to be stretched anteroposteriorly with ero-

sion of the clinoids rather than first ballooned as with primarily intrasellar lesions and the visual system is often affected early and irregularly. The brain is slowly distorted by progressive growth and hypothalamic symptoms are common. Neurological texts should be consulted for a discussion of other intracranial tumors which must be distinguished from cranio-pharyngiomas and which may produce similar damage directly or indirectly.

With gross injury to the hypophysis of whatever origin the gonads, adrenal cortex and thyroid glands are likely to show atrophic changes and the liver and other viscera to be small (splanchnomia) in contrast to the splanchnomegaly seen in acromegaly.

**Symptoms, Signs and Course** The appearance of the various signs and symptoms depends in part upon the size of the lesion and the rate of its development. Ordinarily gonadal deficiencies occur most readily those of the thyroid and adrenal cortex in succession thereafter. Animal experiments have recently suggested that this sequence is more nearly related to progressive destruction of greater and greater amounts of pituitary tissue than to sequential injury of specific areas in the gland (Ganong and Hume). Thus after postpartum necrosis the menses may not return. With chromophobe adenomas amenorrhea is often the first stigma. The atrophy of the gonads and secondarily of the genitalia is profound in any severe grade of hypopituitarism. As judged in children growth deficits occur relatively easily. In adults the margins of safety within the gland for growth hormone production are hard to judge. Hypoglycemia may occur at the time of postpartum necrosis and may lead to coma and may urgently require the use of glucose in treatment.

Atrophy of the skin is common. There is infantile smoothness, dryness and a fine wrinkling which when extreme gives that appearance of precocious aging (geroderma) that so struck Simmonds. The subcutaneous fat is usually well preserved although on occasion when weight loss is great it may largely disappear. Body hair is usually reduced and loss of pubic hair, the beard and axillary hair given time and a severe lesion is common and of diagnostic significance. These atrophic skin changes are partly due to reduction in androgen secretion although the role of loss of the growth hormone is not clear. The skin is rarely puffy as in myxedema despite the commonly reduced basal heat production

which may reach levels as low as minus 40 for long periods. Rarely however typical myxedema appears (*pituitary myxedema*). Radio-iodine uptake by the thyroid gland and serum precipitable iodine are decreased. These indicators however may not be as much depressed as in primary hypothyroidism nor is the serum cholesterol as consistently elevated. It is likely that residual thyroid activity remains in man as in lower forms after destruction of the hypophysis.

The skin is commonly pale with a faint yellowish cast occasionally but by no means always due in part to a normocytic anemia and tans poorly. Even with manifest suprarenal deficiency Addisonian pigmentation does not occur. It is now apparent that a melanocyte stimulating hormone (or hormones) secreted by the pituitary body and detectable in serum and urine is present in excess when the adrenal is directly damaged (Sulman 1952, Lerner and Takakashi 1956). This agent when given to man darkens the skin (Lerner). It may represent either an intermediate lobe secretion or the action of the melanocyte stimulating moiety of the ACTH molecules. In any event the effective hormone can no longer be secreted in excess in response to whatever adrenal cortical deficit results from pituitary failure.

Weakness and loss of energy to the point of incompetence and mental apathy are common although on occasion performance is amazingly good despite substantial endocrine deficits. Psychoses may occur. Hypotension is often present with orthostatic exaggeration and syncope may occur. Water diuresis is slow little or no increase of urine volume occurring in 4 hours after the ingestion of a liter or more of water. Excesses of water readily induce water intoxication. Though adrenal cortical defects contribute to these peculiarities outstanding adrenal insufficiency is not regularly present. Abnormalities in the concentration of serum electrolytes typical of Addison's disease are not usually seen. In the studies after hypophysectomy for cancer it has been noted that even salt restriction may be well tolerated (Lipsett *et al* 1957). The adrenal cortex continues to secrete aldosterone in the absence of the pituitary body and can increase this secretion when needed. Reduction in urinary sodium and chloride excretion results (Luetscher *et al* 1956, Maclean *et al* 1957). In long standing pituitary disease aldosterone secretion may be less than adequate and weakness and hyponatremia fol-

low salt restriction (Luetscher 1956) It is likely that the aldosterone secreting mechanism requires a degree of anterior lobe sustenance in the long run Excesses of urinary sodium and chloride after salt restriction as in true Addison's disease (Loeb 1933) may well occur although Lipsett Pearson *et al* have found the earlier data in hypopituitarism defective and noted that water intoxication alone may cause hyponatremia and weakness Save for these peculiarities in the behavior of sodium chloride and potassium the adrenal crises of hypopituitarism are much like those of Addison's disease They are characterized by anorexia nausea and vomiting prostration hypotension and fever They may occur spontaneously or may be precipitated by stress or by the sudden withdrawal of cortisone The activity of the thyroid hormone predisposes to adrenal incompetence

Urinary corticoids are characteristically low in hypopituitarism Urinary 17 ketosteroids may be low or virtually absent depending on the duration and extent of the adrenal and gonadal (testicular) defect Hypoglycemia may be troublesome emerging especially after prolonged fasting and is often readily induced by small doses of insulin This latter procedure is dangerous As previously noted both the growth hormone and the adrenal steroid or steroids governed by adrenocorticotrophin contribute to the control of carbohydrate metabolism and to opposition to insulin It is not always clear how much loss of each contributes to the defects of hypopituitarism

Anorexia to some degree is common but the metabolic requirements are low and conspicuous loss of weight may not occur More rarely loss of weight is substantial and contributes an important element to an appearance of cachexia Progressive obesity is rare in hypopituitarism alone and he speaks hypothalamic injury when it does occur (see Frohlich's Syndrome)

With tumors the endocrine aspects may be completely dominated by the mechanical effects of the neoplasm and reduction in visual acuity to blindness headache and the various other expressions of an expanding intracranial lesion come to preoccupy the patient and to demand concentrated attention

**Diagnosis** \* The milder forms of hypopituitarism are most likely to escape detection The history of obstetric accident with collapse or hemorrhage points to the possibility of postpartum necrosis and should always be sought Anorexia nervosa affects

chiefly young females and the considerable emaciation the maintenance or increase of body hair the restless behavior and the manifest emotional disorder form a general clinical picture usually quite distinct from that of Simmonds disease Genuinely retarded sexual development in either sex requires investigation of the possibility of gross pituitary disease Amenorrhea in women of previously normal menstrual habit should lead to consideration of gross pituitary disease and the presence of fine hairless skin with reduction or loss of axillary or pubic hair is especially suggestive Films of the sella usually show distinct ballooning and enlargement if a chromophobe adenoma is responsible Calcification in the region of the sella suggests the possibility of a craniopharyngioma Urinary gonadotrophin studies may be helpful since the values are high in early natural menopause low in primary pituitary disease

With adequate clinical or radiological evidence of pituitary disease distinctions can readily be made between primary thyroid and adrenal insufficiency and the deficiencies of these glands which ensue from hypophyseal failure Without such aids (there are many pituitary lesions which do not cause sellar enlargement) differentiation may be extremely difficult Primary adrenal insufficiency Addison's disease is usually associated with increased pigmentation of the skin which is rarely if ever present in the secondary adrenal insufficiency of hypopituitarism A logical basis for this difference is provided by the demonstration of increased blood concentrations of melanocyte stimulating hormone (MSH) in patients with primary adrenal cortical failure in whom the normal inhibitor of ACTH and MSH secretion by the pituitary is lacking (Lerner Sulman) In contrast patients with Simmonds disease may be supposed to have a relative deficiency of MSH indeed they often exhibit a pallor out of proportion to the moderate degree of anemia usually present The difficult problem in Simmonds disease is to establish with certainty whether or not secondary adrenal insufficiency exists This is of obvious importance in planning replacement therapy Low urinary steroid excretion values are the rule in patients with hypopituitarism but this abnormality may be due in part to reduced thyroid and gonadal function and to the poorly understood changes brought about by a chronic debilitating disease Testing with adrenocorticotrophin has been used in several clinics Infusion of 25 USP units intravenously over

\* Revised by Dr Nicholas M Christy

periods of four to eight hours may be expected to induce subnormal but definite increases in urinary and plasma 17 hydroxycorticosteroids and depression in the concentration of blood eosinophils below 50 per cent of the original value. If the atrophy due to pituitary defect is of long standing repeated stimulation may be required before a response is secured. In primary adrenal cortical insufficiency i.e. Addison's disease there is usually no steroidal response to repeated ACTH testing which may partly account for the frequency of allergic reactions to corticotrophin in the Addisonian patient and for the occasional precipitation of adrenal crises in this group. In general this procedure should be used with caution if at all in those with pituitary disease to assess the state of the adrenals and should be avoided in primary adrenal disease. Other provocative tests such as salt with drawal water loading and tolerance to insulin may be abnormal in both primary and secondary adrenal cortical failure and in primary hypothyroidism. They are therefore of limited differential diagnostic value and may be dangerous to the hypopituitary subject. As an index of the integrity of the pituitary adrenal system eosinophil response to epinephrine is of uncertain validity (Thorn) especially in view of the demonstration that this amine does not cause increased adrenal cortical secretion in man (Sandberg *et al*).

In thyroid deficiency secondary to pituitary failure the patient typically presents the depressed basal metabolic rate of hypothyroidism without the soft tissue swellings of myxedema although skin lesions are microscopically identical in primary and secondary hypothyroid states. Poor tolerance to thyroid in myxedema should lead to suspicion of anterior lobe deficiency and is probably caused by the associated adrenal defect. On rare occasions however primary thyroid disease itself leads to adrenal deficit of clinical and anatomical significance and the cautious use of thyroid is beneficial rather than harmful. Amenorrhea especially if genital atrophy is marked suggests hypopituitarism; menorrhagia may suggest hypothyroidism. Serum cholesterol levels tend to be lower in secondary than in primary hypothyroidism but in many instances of Simmonds disease concentrations of 300 to 600 mg per 100 ml are encountered. Uptake of radioactive iodine is low as a rule but may for unknown reasons be normal in the face of clinical thyroid insufficiency and low levels of serum

precipitable iodine. Response of the thyroid to intramuscularly administered thyrotrophin (TSH) measured by increments in radiiodine uptake protein bound iodine or basal metabolic rate is suggestive of secondary hypothyroidism. However atrophy of the thyroid due to pituitary defect of long standing may respond slowly to TSH as does the secondarily atrophied adrenal cortex to ACTH (*vide supra*). Available preparations of TSH appear to cause untoward reactions on occasion.

It should be emphasized that the numerous tests alluded to above have limitations and are often attended by difficulties in execution and in interpretation. They have their chief utility as adjuncts to not as substitutes for due attention to history and physical examination.

**Treatment.** Chromophobe adenomas may be less sensitive to irradiation than chromophile tumors but this therapy should be tried in the hope of arresting the process. Craniopharyngiomas are still less sensitive. Significant restoration of pituitary function is rare. Progressive loss of vision despite irradiation or other evidences of continued intracranial expansion may require attempts at surgical reduction of the tumor mass. By virtue of the location of the tumor the approach is difficult, hazardous and often unsuccessful.

*The endocrine defects are best managed by substitution therapy for the dependent glands.* If the adrenal cortical defect is latent as is commonly the case both the wisdom and the usefulness of vigorous treatment may be considered sub judice at this time. General well being is then the chief criterion of response and this is of course influenced by many factors including subjective ones. When the adrenal insufficiency is manifest under ordinary living conditions the treatment corresponds to that for Addison's disease (see Addison's disease). Although sustained treatment with ACTH in feasible injections must be given daily and cortisone or hydrocortisone 12.5 to 50 mg daily in divided doses orally will usually be preferred. Potassium deficits should be guarded against. It must be remembered that cortisone will depress residual adrenal function so that the gain from treatment must be clear and any discontinuance gradual and guarded. ACTH may be used to restore the depressed adrenal. In manifest crises of adrenal insufficiency treatment corresponds to those of primary Addison's disease. ACTH may be used to support and restore the adrenal cortex but it may not work quickly enough.

if the adrenals have long been atrophic and should not be counted on as a sole measure. Preparations of ACTH and their use are cited briefly under adrenocorticotrophin. In general the patient with hypopituitarism should be protected against those events known to put a strain on the pituitary-adrenal axis. ACTH may serve from time to time to aid in this protection when the strain such as a surgical operation is unavoidable.

Frequent feedings of carbohydrate in day-to-day management and the use of intravenous glucose for emergencies may be essential for the control of hypoglycemia. Cortisone may be expected to protect against such hypoglycemic episodes and to contribute to their control. Thyroid may be helpful in sustained treatment but the reasonable integrity of the adrenal cortex should be assured or any deficiency provided for in advance. Dosage should be small at first (6 mg to 15 mg daily) and increased slowly to 30 or perhaps 60 mg daily. On rare occasions unexpected collapse apparently of adrenal origin may follow vigorous treatment with thyroid. Androgens (testosterone propionate 25 mg two or three times weekly by injection; methyl testosterone 20 to 50 mg daily orally perhaps somewhat less by linguets) may be used to enhance masculine secondary sex characteristics. Although anabolic effects of protein metabolism are demonstrable, opinion differs as to the general gain from such influences in adult Simmonds disease. Interpretations of increased well-being and strength are governed by subjective factors and are greatly affected by a complex metabolic situation. While chorionic gonadotrophin would appear more elegant than androgens stimulating rather than replacing the testes its advantages do not appear real enough at this time. Repair of sperm formation by this gonadotrophin has not been shown with any regularity. It should not be forgotten that some patients are best left untreated if the external demands can be adjusted to their capacities.

#### **HYPOPITUITARISM DURING CHILDHOOD (INCLUDING ATELEIOSIS)**

(Pituitary Dwarfism)

Gross pituitary defect arising during childhood is expressed by retardation of somatic growth in addition to the endocrine deficiencies previously cited. This impairment of growth is relatively uniform throughout the skeletal, visceral and cardiovascular systems yielding a small but rela-

tively harmoniously developed person whose childish proportions and contours mark the time of growth arrest for years to come (Fig 77). The cartilaginous epiphyses remain unossified for long periods. The secondary gonadal insufficiencies contribute in their own characteristic ways to the fixation of the sexual attributes of childhood. Later the atrophic skin may be wrinkled superimposing an incongruous aspect of aging. The profound impairment of the development and function of the central nervous system seen in cretinism does not occur nor does the myxedematous infiltration of the subcutaneous and submucous tissues so characteristic of juvenile myxedema appear to be frequent. The several metabolic consequences of adrenal defect are less conspicuous than in Addison's disease and must be sought. On occasion a pituitary tumor can be demonstrated more often perhaps careful physiologic studies will create a strong presumption for pituitary responsibility.

Autopsy experience is limited. Cranio-pharyngiomas are the most common tumor (see Etiology of Hypopituitarism) and are rarely intrasellar (Erdheim). Cysts of a developmental sort are known including those occurring between separated anterior and posterior lobe anlagen which remain in positions indicating arrest of embryologic procession (Priestel). Simmonds noted fibrosis of unknown origin. It is by no means clear that a full histological account of the real varieties of pituitary defect has been given and one misses descriptions of aplasia or hypoplasia of a pituitary cell line analogous to that in the hereditary dwarfism of Smith and MacDowell. Familial associations of growth defects are common in man.

The establishment of diagnosis based on etiology is especially difficult when growth alone is defective, sexual development normal and other endocrine disorders not conspicuous. Such dwarfs are often termed primordial and held to be small but otherwise normal persons analogous to the pygmy races of man. The term "constitutional" is often used to imply a peripheral tissue growth defect rather than a primary pituitary disorder. Though such interpretations are reasonable it must be recalled that neither autopsy experience nor assays for growth hormone nor measurements of response to growth hormone suffice now to place them beyond question. Throughout the entire problem of dwarfism this interplay of tissue response and hormonal impetus is imperfectly understood. The term

periods of four to eight hours may be expected to induce subnormal but definite increases in urinary and plasma 17 hydroxycorticosteroids and depression in the concentration of blood eosinophils below 50 per cent of the original value. If the atrophy due to pituitary defect is of long standing repeated stimulation may be required before a response is secured. In primary adrenal cortical insufficiency i.e. Addison's disease there is usually no steroidal response to repeated ACTH testing which may partly account for the frequency of allergic reactions to corticotrophin in the Addisonian patient and for the occasional precipitation of adrenal crises in this group. In general this procedure should be used with caution if at all in those with pituitary disease to assess the state of the adrenals and should be avoided in primary adrenal disease. Other provocative tests such as salt with drawal, water loading and tolerance to insulin may be abnormal in both primary and secondary adrenal cortical failure and in primary hypothyroidism. It must be remembered that cortisone will depress residual adrenal function so that the gain from treatment must be clear and any discontinuance gradual and guarded. ACTH may be used to restore the depressed adrenal. In manifest crises of adrenal insufficiency treatment corresponds to those of primary Addison's disease. ACTH may be used to support and restore the adrenal cortex but it may not work quickly enough.

in some cases before notable weight loss but with the onset of emotional disturbance suggests an interpretation analogous to that of the amenorrhea of psychoses. The deficiency in gonadotrophin secretion is thus considered secondary in part to starvation and in part to disturbed mental state.

The few autopsies have shown no gross or microscopic pituitary disease. Clinical studies of endocrine function have usually yielded evidence of reduced hormonal activity but the obvious personality disorder generally renders the distinction from Simmonds disease easy. Urinary estrogen levels are reportedly low and vaginal smear shows no cornified cells. The basal metabolic rate is low often markedly so, the serum cholesterol normal and thyroidal uptake of  $I^{131}$  normal. Urinary 17-ketosteroid excretion tends to be reduced but ketosteroid rise after corticotrophin administration is normal. In the recovered patients most of these indices of endocrine activity revert to normal.

The disorder may develop after dieting for obesity. The aversion to food is profound or if hunger is experienced satiety comes so quickly that eating provides little more than a nibbling of sweet insufficient juices perhaps enough to prevent ketosis but far from enough to meet energy requirements. A variety of disagreeable abdominal sensations occurs including nausea. Vomiting is common if food is forced and is often self-induced. The loss of weight is extreme often reducing the victim to the contours of her bony skeleton. Unlike Simmonds disease however, sexual hair is retained and even a fine general hypertrichosis may develop. Despite her pitiable plight the victim is often active or restless with an even cheerful preoccupation with trivia. Sustained effort is difficult and pressure especially to eat may lead to every variety of deceit to avoid compliance. Moderate anemia, hypoproteinemia and nutritional

edema may develop. Death may occur from starvation after years of debility.

Treatment comprises reeducation of the patient with persuasion to eat together with whatever gentle force the physician can command. Psychiatric care is desirable if judicious but the results are variable. In a few hands they seem good indeed but great patience is necessary and failure is common enough. Endocrine treatment has not been established as valuable.

FIG 77 Two children of the same age. The one on the right is normal. The one on the left had a craniopharyngioma at the age of 11. Note the complete cessation of growth.

*ateleiosis* (Gilford) which is wisely non-descript might well be reserved for the generality of dwarfs both with and without sexual defects until the extent of true hypopituitarism in explanation can be fully ascertained.

Primary pituitary disease in girls must be distinguished from the much more common association of shortness of stature with ovarian defect. The associated variegated congenital anomalies often include the cubitus valgus and webbed neck described by Turner (Turner's syndrome). These subjects show no evidence of hypopituitarism on detailed study and urinary gonadotrophins are high. Studies recently initiated by Barr often show none of the typically female chromatin-like bodies near the nuclear membrane of the cell. The cells thus resemble those of males and the subjects have been interpreted as genetic males. As no positive identification of masculine nuclei is possible now this interpretation is presumptive and should be held as a working hypothesis only. (See the section

on Diseases of the Sex Glands for further discussion.)

The treatment of hypopituitarism in childhood is much the same as in adult life. Some increase in stature may be expected from the use of androgens although full restoration of normal growth is not to be expected. Use of androgens in the female must be carefully guarded.

### FROHLICH'S SYNDROME

(*Adiposogenital Dystrophy*)

Since Frohlich's (1901) account of mild obesity and retardation of genital development in a boy with the visual field defects of a pituitary tumor the association of obesity and hypogonadism has been termed Frohlich's syndrome although *adiposogenital dystrophy* is more precise. Erdheim's view that the progressive obesity is due to hypothalamic lesions rather than to hypopituitarism has received modern experimental support. Excessive eating is the most important factor in producing this obesity. Genital dystrophy has similarly been induced by circumscribed hypothalamic lesions but in this instance secondary hypopituitarism presumably occurs. The term "Frohlich's syndrome" may be properly applied to the pituitary or juxtapituitary lesions in which the association of obesity and hypogonadism is due to a common cause. Hypogonadism *per se* does not give rise to progressive obesity. Obesity in children before puberty should not be termed Frohlich's syndrome nor can hypopituitarism be often held responsible for their obesity. Obesity of hypothalamic origin will respond to dieting if appetite can be controlled.

### ANOREXIA NERVOSA\*

Anorexia nervosa is a chronic disorder chiefly of young women and is characterized essentially by an obsessive aversion to food leading to emaciation. Amenorrhea is the rule. Gull described the disease and attributed it to a functional disorder of the nervous system an interpretation which survives. The profound emotional and character disorder the tendency to develop with the assumption of independent adult life and the common history of grievous personal difficulties support this view together with the recovery that may be made under fortunate medical and general environmental conditions. The emotional disorder is held to be a neurosis with compulsive anxiety depressive and often schizophrenic features. The early onset of the amenorrhea

9α fluorohydrocortisone	++++	++++	5-10 × DOC	5-10 × DOC	++++	++++	++++

hydrocortisone and related compounds are very potent mineralocorticoids. The latter steroids also have glucocorticoid activity but cannot be used as such since their salt retaining activity is so great as to overshadow their hydrocortisone like activity.

**Steroid Biogenesis** With this array of known substances extractable from adrenal tissue the question has been debated whether one two three or all the steroids were secreted by the adrenal cortex. How ever since the first demonstration by Bloch of the conversion of isotopically labeled cholesterol to progesterone in the pregnant woman and a series of studies by Hechter, Pincus, Dorfman, Samuels and others on the mechanism of steroid synthesis within isolated adrenal tissue the riddle of the multitude of adrenal steroids seems closer to solution.

Cholesterol is the major precursor in the formation of the adrenal steroids. The first step in steroidal synthesis from cholesterol is the scission of the side chain resulting in the formation of  $\Delta^5$ pregnenolone. The next step is the conversion of  $\Delta^5$ pregnenolone to progesterone by the action of the enzyme 3  $\beta$ -ol hydrogenase. Progesterone apparently is the mother steroid for the synthesis of the other hormones (Fig. 79). Adrenal tissue contains a series of enzymes which can hydroxylate the progesterone molecule at the C 17 (17 $\alpha$  hydroxy progesterone), C 21 (Compound S) and C 11 position in a step-like fashion and thus synthesizes hydrocortisone. Aldosterone is probably synthesized from corticosterone. It has also been demonstrated that testosterone may be derived

from the cleavage of the 17 $\alpha$  hydroxy progesterone side chain and can give rise to estradiol.

These biochemical transformations can occur in the presence of cell free prepara-

Fig. 79

## STEROID PHYSIOLOGY AND METABOLISM

**Introduction** In the relatively short time since the first steroidal hormone was isolated an impressive amount of information has been accumulated regarding the role of the adrenocortical and gonadal steroids in many bodily mechanisms. The introduction of specific and sensitive analytical methods for the determination of steroids and their metabolites in biological fluids has furthered knowledge relative to the precise mechanism of synthesis within some of the endocrine glands. The sum total of this investigative endeavor has produced basic information in this field which has helped explain many of the manifestations of adrenal diseases.

Over forty different steroids have been isolated from adrenal tissue. These steroids

can be classified according to the number of carbon atoms in the molecule as is shown in Figure 78. The C21 steroids are commonly referred to as corticoids and are pregnane derivatives; they can be subdivided further according to the number of oxygen atoms. The C19 steroids are androgens or androstane derivatives. The C18 steroids are estrogens.

The adrenal steroids may also be classified according to their physiological activity which to a degree is dependent upon the chemical structure (Table 1). The hormones isolated from adrenal tissue fall into five general biological categories. These are: (1) *The glucocorticoids: hydrocortisone or cortisol and corticosterone.* The important physiological effect of this class of adrenal steroids is to promote gluconeogenesis from the catabolism of protein. They also inhibit the action of insulin. Renal blood flow is increased by the administration of steroids of this class and they also protect adrenalectomized animals against stress. Hydrocortisone and cortisone have a very potent anti-inflammatory effect. (2) *The mineralocorticoids: aldosterone and desoxycorticosterone.* Although these hormones are very effective in maintaining the life of adrenalectomized animals under ideal laboratory conditions, they are not very effective in protecting against stress. Their primary effect is to promote the retention of sodium and the excretion of potassium by the renal tubule. (2) *Androgens: androstenedione, 11 $\beta$ -OH androstenedione.* The function of these steroids is not clear, although androstenedione is a very potent androgen having approximately one half the biological activity of testosterone. (4) *Progesterone* and (5) *Estrone.*

Other steroids which have been isolated from adrenal tissue are biologically inert and still others have been found in insufficient quantity for biological assay.

In addition, several new steroids have been synthesized which are somewhat different in chemical structure from the naturally occurring ones. Prednisone, prednisolone, and methylprednisolone are powerful glucocorticoids, whereas 9 $\alpha$ -fluoro-

FIG 78 Steroids isolated from adrenal tissue

lation comes from the acetate moiety. There is however no complete agreement on this point.

**The Catabolism of the Steroids** From analyses of human adrenal vein blood it has been established that the adrenal cortex secretes hydrocortisone, corticosterone, aldosterone and trace amounts of  $11\beta$  OH androstenedione and  $\Delta^4$ androstenedione. (Although dehydroisoandrosterone has not been identified in adrenal vein blood it is the most abundant C19 steroid found in peripheral blood.) It is possible that under certain conditions precursors of these steroids also may escape into the circulation. These secreted hormones circulate in the blood loosely bound to proteins and are degraded by the liver. Complete destruction of the phenanthrene nucleus does not occur. The steroids are chemically transformed to a more reduced state and are metabolized in accordance with certain general principles (Fig. 80) as follows: (1) The  $\alpha\beta$  unsaturated carbonyl group in ring A is reduced to a saturated ketone or alcohol. (2) The carbonyl group at C20 may be unaltered or converted to a secondary  $\alpha$  or  $\beta$  hydroxyl group. (3) The tertiary C17 hydroxyl group plus a vicinal oxygen at C20 can be cleaved to a C19 steroid and excreted as a 17 ketosteroid. (4) The hydroxyl group at C21 also may be reduced.

In addition to the catabolic transformations the metabolites are conjugated as glucuronates, sulfates or other forms as yet

unidentified. They are excreted mostly as conjugates. Of the various excretory pathways available for the catabolic steroidal products in man the urinary route is by far the most important. These urinary products can be analyzed and may give valuable information relative to the state of adrenocortical function.

**The Urinary Steroids** The more abundant C21 urinary steroids are shown in Figure 80. These are mostly catabolic products of hydrocortisone. All except cortol and cortolone may be determined chemically by modifications of the Porter-Silber method for 17 OH corticosteroids. Since cortol and cortolone are important urinary metabolites this is a major drawback to the Porter-Silber method. However, Norymberski has recently devised a method for determining the 17 OH corticoids which also detects cortol and cortolone. The metabolites so detected are referred to as "ketogenic steroids" since in the method of analysis the side chain is cleaved by oxidation to a 17 ketosteroid.

The major urinary 17 ketosteroids are shown in Figure 81. Those 17 ketosteroids containing an oxygen group at C11 are degradation products of hydrocortisone and comprise about 20 per cent of the total. The secretory precursors of androsterone, etiocholanolone, and dehydroisoandrosterone are not completely known. Androsterone and etiocholanolone do arise from the transformation of testosterone and  $\Delta^4$ androstenedione, but these precursors could

FIG. 81. Precursors of the most abundant 17 ketosteroids.

FIG 80 Major urinary 17 OH corticosteroid metabolites of hydrocortisone

tions Information is also available relative to the conditions necessary for activity of some of the enzyme systems involved

There is evidence also that acetate may act as a precursor for the adrenal steroids without intermediary formation of cholesterol This has definitely been shown to be the pathway of estrogen synthesis but a corresponding pathway for the formation of C 21 and C 19 steroids in the adrenal glands has not been conclusively demonstrated

**The Control of Corticotropin Secretion**  
Since the classic demonstration by P E Smith that the adrenal the thyroid and the gonads are dependent upon pituitary secretions chemists have attempted to isolate the tropic hormones in pure form This has been successful for the adrenocorticotrophic hormone which has been shown to be a polypeptide Whereas ACTH is effective in stimulating the secretion of the glucocorticoids the secretion of aldosterone seems to be independent of pituitary control

There is a basic level of ACTH secretion by the pituitary In response to many different types of stress the pituitary secretes a greater amount of ACTH which in turn results in the increased secretion of the adrenal steroids that are necessary for homeostasis ACTH secretion is dependent upon several factors (1) *Hormonal control* The level of circulating adrenal steroid is a controlling factor of ACTH secretion In the absence of circulating steroids *eg* adrenal insufficiency increased amounts of ACTH have been detected in the circulating blood On the other hand the prolonged administration of cortisone leads to adrenal

atrophy This is indicative of ACTH suppression (2) *Hypothalamic control* There are centers in the hypothalamus probably in the median eminence which also control the release and the rate of the synthesis of ACTH It has been demonstrated in the experimental animal that small destructive lesions restricted to the median eminence prevent the secretion of ACTH in response to stress In addition a protein like substance has been isolated from hypothalamic tissue which is capable of stimulating ACTH secretion by the pituitary This hypothalamic control is probably mediated by a neurohumor which is transported via the hypophyseal portal system to the pituitary gland

**Action of ACTH on the Adrenal Cortex**  
The administration of ACTH causes an almost immediate fall in the concentration of both cholesterol and ascorbic acid in the adrenal cortex It has been claimed by Hechter that when ACTH is incubated with adrenal tissue there is a greater increase in the production of hydrocortisone when cholesterol is used as a substrate than if progesterone is used Consequently Hechter infers that ACTH has its effect on the biosynthetic mechanism at a point prior to the production of progesterone perhaps by cleaving off the side chain of cholesterol and facilitating the synthesis of pregnenolone In addition it is claimed that when acetate is used as a precursor the addition of ACTH to adrenal slices has no effect on the output of hydrocortisone The latter observation would indicate that the small amount of hydrocortisone which may be produced in the absence of pituitary stimu-

## DISEASES OF THE ADRENAL GLANDS

## Introduction

The first known description of the adrenal glands is recorded in *Opuscula Anatomica Venetus* (1563) by the great anatomist of the Renaissance Bartholomaeus Eustachius Scantosevercrinatus. It is of interest that Eustachius described these structures as glands although their function was not at all understood. Meckel's studies in 1806 deserve particular consideration because he introduced new methods of studying adrenal gland function by destroying the organ within living animals and by studying the organ in different types of animals. It was not until 1855 however in Thomas Addison's classic description of a clinical syndrome which resulted from destruction of the adrenal glands that the vital function of these organs was really appreciated. Shortly thereafter Brown Sequard demonstrated conclusively that complete removal of both adrenals was followed promptly by death of the experimental animal. The studies of Vulpian, Oliver, Schaeffer, Abel, Takamine and Aldrich ultimately resulted in isolation of epinephrine from the adrenal medulla but since the relationship between medullary secretion and cortical secretion was not understood it was with some disappointment that epinephrine was found to be ineffective in the treatment of Addison's disease. This observation however stimulated further experimental work in which it was demonstrated that the complete removal of one adrenal accompanied by the destruction of the medulla of the remaining adrenal did not give rise to the classic signs and symptoms of adrenal insufficiency. From these observations it appeared that the "life maintaining" substance liberated by the adrenal was derived from the cells of the cortex.

In 1927 Hartman, MacArthur and Hartman and Rogoff and Stewart independently reported the preparation of adrenal cortical extracts which were capable on injection of prolonging the survival period of adrenalectomized animals. In 1930 Swingle and Pfaffner and Hartman and Brownell independently described methods of preparing

adrenal cortical extracts of much greater potency.

The classic studies of Loeb and Harrop demonstrated the beneficial effect of sodium salts in the treatment of patients with Addison's disease. Not only was a diet of high sodium content beneficial but the studies of Truszkowski and Zwemer and Wilder demonstrated the advantages of a low potassium intake in patients with adrenal insufficiency.

In 1933 both Kendall and Grollman obtained crystalline material from adrenal cortical extracts. This material appeared to have cortical hormone like activity. Some what later Reichstein isolated a crystalline compound from the adrenal cortex which had cortical hormone like activity and which he identified and named "corticosterone". Subsequently Kendall demonstrated that the active compound which he had described was identical with that of Reichstein's corticosterone. In 1937 Steiger and Reichstein announced the synthesis from stigmasterol of a steroid compound *desoxycorticosterone acetate*. This compound was found to have cortical hormone like activity and was noted to be closely related chemically to progesterone. The development by Reichstein, Kendall and Sarret of procedures for placing an oxygen atom on the 11 and 17 carbon atoms of the steroid nucleus led to the preparation of cortisone and hydrocortisone for therapeutic use. In 1952 Simpson, Tait and Bush employing a chromatographic separation were able to isolate a very potent sodium retaining factor from adrenal venous blood. This they termed "electrocortin". The collaboration of Wettstein, Neher, von Ew, Schneider and Reichstein with Simpson and Tait resulted in 1954 in the elucidation of the chemical structure of electrocortin as the 18 aldehyde of corticosterone. It was accordingly given the name of aldosterone. The synthesis of aldosterone was achieved by Schmudlin, Anner, Billeter and Wettstein in 1955 and its identification as the sodium retaining factor in the urine of patients with nephrosis and heart failure was subsequently established by Luetscher, Neher and Wettstein.

account for only a small amount of the total

**The Assessment of Adrenal Function** The normal values for the plasma 17 OH corticosteroids and urinary 17 ketosteroids 17 OH corticosteroids and ketogenic steroids are presented in the table of Normal Values of Clinical Importance (Appendix) The values are usually depressed in both primary and secondary adrenal insufficiency but there may be an overlap with levels obtained in endocrinologically normal persons Decreased concentrations of urinary steroids to the administration of the chronic diseases The finding of low levels of urinary steroids in itself is not diagnostic of adrenal insufficiency However the response of both the plasma and urinary steroids to the administration of exogenous corticotropin may be of great value in assessing adrenal function since the administration of ACTH results in no increase in these values in the absence of functioning adrenals

The corticosteroids are usually elevated in Cushing's syndrome whereas there may be little or no increase in the urinary 17 ketosteroids in this condition On the other hand the various virilizing syndromes are characterized by the finding of elevated 17 ketosteroids and normal or even low 17-OH corticosteroids

followed complete relief of the associated hypertension

Pheochromocytomas are comparatively rare. In 1950 Smithwick collected 270 cases from the literature (67 per cent demonstrated only at autopsy). A recent apparent increase in the incidence of these tumors may be accounted for by the use of new diagnostic agents by careful search among hypertensive patients for curable forms of hypertension and by the increased opportunity to detect chromaffin tumors when operations are being performed on the thoracolumbar sympathetic chain for the treatment of hypertension.

Pheochromocytomas occur in all age groups but are more frequent in adults. There is no sex predilection.

**Pathology.** In 10 to 20 per cent of cases the tumors are multiple. In a similar number of instances the tumors have been found outside the adrenal in chromaffin tissue in the paraganglia along the retropleural and retroperitoneal chains of the sympathetic nervous system in the carotid bodies or the organs of Zuckerkandl. An associated neurofibromatosis has been observed in 5 per cent of cases. Approximately 10 per cent of the tumors are malignant and metastasize to regional and thoracic lymph nodes, liver and skeleton.

The tumors vary in size but are frequently quite small. They are usually lobulated, highly vascular and well encapsulated. The cut surface is yellowish brown in color and frequently shows evidence of hemorrhage and cystic degeneration. Microscopically the tumor cells are large, irregular or polyhedral in shape and have a granular cytoplasm.

**Clinical Picture.** The manifestations of pheochromocytoma are the result of an increased secretion of norepinephrine and epinephrine. Two distinct syndromes occur: one associated with intermittent or paroxysmal hypertension and the other characterized by persistent hypertension.

In 35 to 50 per cent of cases classic paroxysms, "adrenosympathetic crises" occur. These may be precipitated by such events as emotional upsets, physical exertion or changes in posture. Early the attacks tend to occur at long intervals and last only a few minutes. Later they may be more frequent and severe, lasting many hours. The attacks are characterized by severe anxiety, throbbing headache, forceful palpitation, tremulousness, visual blurring, nausea, sometimes vomiting, occasionally retrosternal chest pain and a

rise in blood pressure which may attain a systolic level of 300 mm of mercury or more. The diastolic blood pressure may rise to a level of 175 mm of mercury. The extremities are cold and often pale, the neck veins distended, the pupils dilated and the skin soaked with perspiration. Hypoglycemia and glycosuria during attacks are common. Prolonged episodes may terminate in a shock-like state with hyperpyrexia and hypotension. Death may occur from pulmonary edema, ventricular fibrillation or cerebral hemorrhage.

In many cases of pheochromocytoma there is sustained hypertension. The course of the disease is not unlike that of essential hypertension with progressive cardiovascular, renal and retinal involvement. The basal metabolic rate is often elevated and frank diabetes may be encountered. Chemical analysis of tumors in these cases usually reveals a marked preponderance of norepinephrine.

**Diagnosis.** This may be established by the history of a typical attack or by deliberately precipitating an attack through change in position or direct pressure upon the tumor. In a small percentage of cases a tumor or a displaced kidney may be palpated in the flank. Pyelography may reveal depression of the renal shadow. Perirenal and more recently presacral insufflation of oxygen have been employed to outline a tumor mass.

Certain pharmacological tests may be of considerable aid in the diagnosis of pheochromocytoma. Two types of test are used. In one the provocative test, a paroxysm of hypertension is precipitated when the blood pressure has been normal. In the other the blocking test, a fall in blood pressure is induced by the use of an adrenolytic compound when the pressure has been elevated. Of the provocative agents, histamine probably provides the most reliable response, but both false negative and false positive responses have been reported. *Histamine phosphate* when given intravenously in a dose of 0.01 to 0.025 mg induces a flush, headache and a slight blood pressure fall in the normal subject. A rise in blood pressure significantly greater than the cold pressor response within two minutes of injection is considered a positive test. This occurs in many but by no means all cases of pheochromocytoma. Sometimes alarming rises in blood pressure occur which may be dangerous in patients with advanced arterial disease. In these instances Regitine 5 mg should be administered intravenously.

## Diseases of the Adrenal Medulla

The cells of the adrenal medulla are of ectodermal origin and arise as do the cells of the sympathetic nervous system from the primitive neural crest. The parent cell is the sympathogone. This cell may differentiate to form a sympathoblast or neuroblast and finally a mature ganglion cell or it may give rise to a chromaffin cell. The latter is so named because of the brown color which the granules of its cytoplasm assume when treated with chromic acid salts.

These cell types are found not only in the adrenal medulla but wherever sympathetic nervous tissue occurs particularly in the ganglia and in the organs of Zuckerkandl at the bifurcation of the aorta. Tumors may develop from any of these cell types.

**Hormones of the Adrenal Medulla.** Epinephrine was the first hormone to be isolated (Abel 1897) and chemically identified (Aldrich 1901). In 1949 von Euler isolated norepinephrine from the adrenal medulla and from adrenergic nerve fibers thereby establishing the existence of two medullary hormones. Structurally these two hormones are catecholamines and differ only in the fact that norepinephrine lacks the N-methyl group possessed by epinephrine (Fig 82). The epinephrine and norepinephrine content of human adrenal medullary tissue has been estimated biologically by von Euler to be 2.4 to 4.0 mg per gm of which 10 to 30 per cent is norepinephrine. The total plasma concentration of epinephrine and norepinephrine is approximately 3 micrograms per liter; norepinephrine makes up approximately 80 per cent of this value. The urine normally contains between 15 and 45 micrograms of catecholamines per day; 85 per cent of this is norepinephrine. The preponderance of norepinephrine in both plasma and urine in the face of a low norepinephrine/epinephrine ratio in the adrenal medulla is thought to reflect the liberation of additional quantities of this humoral agent from adrenergic nerve endings. In contrast to normal medullary tissue in which the predominant hormone is epinephrine, actively secreting adrenal medullary tumors (pheochromocytomas) often contain large amounts of norepinephrine.

Pharmacological studies have shown important differences in the actions of epinephrine and norepinephrine. Both hor-

Norepinephrine

Epinephrine

FIG 82 Adrenal medullary hormones

mones raise the blood pressure but by different mechanisms. Epinephrine causes an increased cardiac output and with the exception of the skin vessels generalized vasodilatation. The cardiac rate increases, the systolic pressure rises but the diastolic pressure shows little change. Norepinephrine on the other hand causes marked peripheral vasoconstriction with a rise in both systolic and diastolic blood pressure. The cardiac output is little altered and the heart rate may be slowed. Epinephrine has a prominent metabolic effect which is possessed to only a very limited extent by norepinephrine. It causes increased oxygen consumption with a rise in body temperature and basal metabolic rate. Furthermore it accelerates hepatic glycogenolysis with a consequent rise in fasting blood sugar levels and often a diabetic type of glucose tolerance curve. Muscle glycogen is broken down more rapidly to lactic acid. Epinephrine causes a significant fall in the level of circulating eosinophils but actual stimulation of the adrenal cortex has not been demonstrated to occur in man.

Despite the important physiological effects of the adrenal medullary hormones the adrenal medulla is apparently not essential for life. It is however a valuable adjunct to the adrenal cortex in aiding the organism to cope with acute stress. In instances of adrenal medullary insufficiency have not been recognized clinically.

### ADRENAL MEDULLARY HYPERFUNCTION (Pheochromocytoma)

Pheochromocytomas are actively secreting tumors arising in the chromaffin tissue of the adrenal medulla or the paraganglia of the sympathetic nervous system. The first description of the association of paroxysmal hypertension and pheochromocytoma was given by Labbe in 1922. In 1927 C. H. Mayo removed such a tumor and there

It contains many mature ganglion cells separated by a network of myelinated or nonmyelinated nerve fibers

#### Neuroblastoma (Sympathoblastoma)

This highly malignant tumor occurs almost exclusively in infancy and early childhood. Except for renal embryoma (Wilms tumor) neuroblastoma is the commonest retroperitoneal malignant tumor of children. In approximately 50 per cent of cases these tumors are extraadrenal arising retroperitoneally or retropleurally in the sympathetic chain the celiac ganglia the organs of Zuckerkandl the cervicosympathetic ganglia or from the substance of the central nervous system. The tumor metastasizes early to regional lymph nodes liver bones and orbit.

Pathologically the tumors are large and cellular. The cut surface is firm with many areas of hemorrhage and necrosis. The cells which are oval with dark brown nuclei and thin rims of cytoplasm are often arranged in rosette fashion and separated by fine fibrils.

The manifestations of a neuroblastoma may be those of a local tumor mass with abdominal enlargement vomiting and pain or they may be those of a generalized malignancy with weakness loss of weight fever and anemia. In one quarter of the cases there is generalized lymphadenopathy. In some instances metastases may introduce the disease and the child may present swellings in the skull proptosis and ecchymoses of the eyelids.

Radical surgery followed by deep x-ray therapy is the treatment of choice. Although the prognosis is poor Farber reported 10 cures in 40 cases treated in the above manner and followed over a ten year period. In some of these children complete surgical removal of the tumor had not been possible.

## Diseases of the Adrenal Cortex

### INTRODUCTION

During the past two decades approximately thirty steroid compounds have been isolated from the adrenal cortex. Six of these which are capable of maintaining life in adrenalectomized animals have been identified: hydrocortisone (Compound F), cortisone (Compound E), corticosterone (Compound D), dehydrocorticosterone (Compound A), desoxycorticosterone (DOC) and the recently isolated aldosterone. Those compounds which possess an alpha ketol side chain (CO-CH OH) at carbon 17 are termed "corticoids." Compounds A, D, E and F and aldosterone which possess an oxygen atom at a carbon 11 are "11-oxygenated corticoids." Compounds E and F are "11-17-oxygenated corticoids."

Hydrocortisone (Compound F) and cortisone (Compound E) exhibit most of the known effects of the adrenal cortex when administered to adrenalectomized human subjects. While these compounds have a relatively weak electrolyte regulating activity when given by mouth or by intramuscular injection they are capable of producing a profound sodium retention when administered continuously by the intravenous route. Desoxycorticosterone while strongly sodium retaining has little effect on intermediary protein fat and carbohydrate metabolism. Aldosterone which is a derivative of corticosterone with an aldehyde group at carbon 18 is twenty to thirty times as active in sodium retention as desoxycorticosterone and appears to be more effective than desoxycorticosterone in its influence on carbohydrate metabolism. Corticosterone (Compound B) and dehydrocorticosterone (Compound A) stand halfway between hydrocortisone and desoxycorticosterone in terms of the physiological activities which they exhibit. Unlike hydrocortisone and cortisone they do not induce an eosinopenia or lymphopenia. Although many steroids have been isolated from adrenal cortical tissue it would appear from studies on adrenal venous blood that the human adrenal cortex secretes mainly hydrocortisone corticosterone aldosterone and an androgenic 17 ketosteroid androstenedione. Of these hydrocortisone is secreted in the greatest amount. Desoxycorticosterone does not appear to be a natural secretory product of the adrenal cortex. Catabolism of the adrenal steroids

**Methacholine hydrochloride** (Mechoyl) when given subcutaneously in doses of 12.5 to 25 mg to a normal subject produces salivation sweating and a transient fall followed by a mild rise in blood pressure. A striking rise in blood pressure may occur when pheochromocytoma is present but as with the histamine test both false negative and false positive tests occur. Alarming reactions may be seen and the subcutaneous administration of 10 mg of atropine sulfate prior to the injection of the Mechoyl is recommended.

Of the blocking agents Benzodioxane and Regitine are the most reliable. **Benzodioxane** (piperoxanhydrochloride) is structurally related to epinephrine. It exerts an antipressor effect while retaining certain sympathomimetic actions. When given intravenously over a two minute period in a dose of 10 mg per square meter of body surface it causes agitation tachycardia flush headache and dizziness. In the normal subject there is a slight rise in blood pressure. When a pheochromocytoma is present the pressure usually falls at least 35 mm of mercury. False positive tests are extremely uncommon although false negatives occur not infrequently. **Regitine** (phentolamine) has a similar antipressor action without unpleasant side effects. When given intravenously in a 5 mg dose a similar blood pressure fall occurs if a pheochromocytoma is present.

In the performance of these tests it is important to have the patient resting quietly to establish a good baseline blood pressure. When sedatives have been administered within twenty four hours of the test false reactions may occur. The responses in uremic patients are unreliable.

In 1950 Engel and von Euler observed a marked increase in the urinary excretion of catecholamines in the presence of pheochromocytoma. This finding has been confirmed by Goldenberg employing a fluorometric technique rather than a biological assay. Recently the histamine test has been combined with blood catechol amine analysis. Elevated levels of catechol amines may be observed two to ten minutes after the administration of 0.025 mg of histamine phosphate given intravenously. Normal subjects and hypertensive patients without pheochromocytoma do not show this reaction.

**Treatment** Surgical excision of the tumor may result in complete remission of symptoms although in certain instances in which the hypertension has been persistent

and of long duration little change in blood pressure may occur following operation. The transperitoneal approach allows satisfactory exploration of all possible tumor sites in the abdomen. Two serious events may occur during operation: (1) The blood pressure may rise to extreme heights or fatal cardiac arrhythmias may occur due to excessive discharge of medullary hormones or (2) following resection of the tumor the blood pressure may fall precipitously and profound shock ensue due to abrupt withdrawal of circulating hormones. Adequate preoperative sedation is important. Anesthetic agents likely to produce serious cardiac arrhythmias in the presence of high epinephrine levels—cyclopropane ethyl chloride—should not be employed. Induction with Pentothal followed by intra tracheal nitrous oxide—ether with high oxygen saturation provides satisfactory anesthesia. Ligation of the blood supply of the tumor before handling will reduce the likelihood of precipitating a hypertensive episode. The latter can be corrected by the use of intravenous Regitine which should be kept ready during the operation and administered when indicated. The precipitous fall in blood pressure which often occurs following ligation of the tumor vessels can be managed by the use of intravenous norepinephrine. During the post operative period NeoSynephrine may be given subcutaneously to correct mild hypertensive episodes. Once the immediate post operative period is over patients usually do well and symptoms and hypertension disappear.

Because of the excellent results of surgical treatment it is of the utmost importance to consider the possibility of pheochromocytoma in all hypertensive patients.

#### NONFUNCTIONING TUMORS ARISING FROM MEDULLARY TISSUE

These tumors may arise from any of the primitive or mature cells of the sympathetic nervous system and the adrenal medulla.

The **sympathoganglioma** is a rare highly malignant tumor which appears early in fancy or intrauterine life. It is a large soft cellular growth which often shows evidence of hemorrhage and necrosis. It metastasizes early to retroperitoneal lymph nodes liver and bone. The prognosis is poor.

The **ganglioneuroma** on the other hand is a small well encapsulated slow growing tumor which occurs in adults and is usually an incidental finding at post mortem.

fluids. It can also be obtained as the acetate in crystalline suspension in saline solution (25 mg per ml) and in the form of scored tablets (20, 10 and 5 mg).

**1 Cortisone** This hormone is available as the acetate (a) as a crystalline suspension in saline solution which is suitable for intramuscular injection and of which 10 ml contains 25 mg of hormone and (b) as scored tablets 5 and 25 mg for oral use.

**3 Prednisone and Prednisolone** These substances are four to five times as potent as cortisone and hydrocortisone and have much less sodium retaining activity. They are available in 5 mg tablets.

**4 Nine alpha fluorohydrocortisone** This substance is approximately 25 times as potent as cortisone and hydrocortisone in carbohydrate activity and exhibits marked salt retaining activity as well. It is available in tablets of 10 and 0.1 mg.

**5 Desoxycorticosterone** This hormone is available in three forms: (a) as the acetate dissolved in sesame oil for intramuscular injection 5 mg of the hormone in 10 ml; (b) as the acetate in the form of tablets known as linguets or buccalets containing 2 or 5 mg of the hormone in inert vehicles for direct sublingual absorption; (c) synthetic desoxycorticosterone trimethylacetate a crystalline suspension of slowly hydrolyzed microcrystals acting for approximately four weeks after intramuscular injection 25 mg once a month being equivalent to 1 mg daily of desoxycorticosterone acetate in oil.

**■ Corticotropin** Corticotropin (ACTH) is available as (a) lyophilized powder 10 to 40 U.S.P. units per vial which can be administered in aqueous solution either intravenously or by intramuscular injection by which route it has a duration of action of six to eight hours or (b) as a long acting gel preparation (duration of action eighteen to twenty four hours) 20 to 80 U.S.P. units per ml. Gel preparations must be kept refrigerated and must be warmed to 50° C before being taken up in a syringe. Since ACTH is a polypeptide sensitivity reactions may be encountered particularly in patients with primary adrenal insufficiency who have not received cortisone.

#### HYPOFUNCTION OF THE ADRENAL CORTEX

The various types of adrenal insufficiency may be classified as follows:

- 1 Acute adrenal cortical insufficiency
  - (a) Adrenal crisis (in patients with Addison's disease)

- (b) Adrenal hemorrhage
- (c) Surgical (following adrenalectomy or resection of hyperfunctioning adrenal tissue)
- (d) Iatrogenic—induced by ACTH, cortisone or hydrocortisone therapy
- 2 Chronic adrenal cortical insufficiency
  - (a) Primary (Addison's disease)
  - (b) Secondary (hypopituitarism)
  - (c) Surgical (following adrenalectomy)
  - (d) Insufficiency associated with an endogenous adrenal hyperplasia

#### ACUTE ADRENAL CORTICAL INSUFFICIENCY

**Adrenal Crisis** An adrenal crisis represents a severe acute exacerbation of Addison's disease. Although present-day substitution therapy has materially reduced the frequency of adrenal crisis, the advent of infection, trauma or gastrointestinal upset in patients with Addison's disease, unless combated by an immediate increase in hormone dosage, may rapidly lead to the development of acute adrenal insufficiency. The classic manifestations of adrenal crisis are anorexia, nausea, vomiting, headache, diarrhea, abdominal pain, dehydration, hypotension, restlessness, marked weakness and lethargy. Hyperpyrexia, often extreme, usually occurs but subnormal temperatures may be encountered even in the presence of infection. Ultimately coma and vascular collapse ensue. It should be emphasized however that in well treated patients, especially those who have received desoxycorticosterone, hypotension and shock may only occur terminally. Laboratory study usually but not invariably reveals hyponatremia, hyperkalemia, hypoglycemia and azotemia.

The necessity for immediate and vigorous treatment of adrenal crisis is strongly emphasized. Therapy is directed at the provision of adequate adrenal cortical hormone, the control of infection and support of the cardiovascular system.

1 A continuous intravenous infusion of 5 per cent glucose in normal saline is started immediately. Hydrocortisone (200 mg) is administered in 5 per cent glucose by a separate intravenous infusion. If an intravenous preparation of hydrocortisone is not available, cortisone acetate is given intramuscularly in an initial total dose of 200 mg (in four different sites). Thereafter the hormone may be given orally and the dosage gradually tapered to a maintenance level of 25 mg per day.

and the role of the pituitary gland in their elaboration and secretion are discussed in the section on Steroid Metabolism

**Functions of the Adrenal Cortex** The functions of the adrenal cortex as mediated by the adrenal cortical steroids are as follows

**Regulation of Sodium Potassium and Chloride Metabolism** The 11 oxygenated corticoids increase the reabsorption of sodium and chloride by the renal tubules and decrease the sodium chloride loss in sweat salivary gland and gastrointestinal secretion. The administration of these compounds results in an initial and inconstant rise of urinary potassium excretion. There may follow a brief period of potassium retention probably associated with the deposition of glycogen in the liver. Thereafter one observes a continued loss of potassium. This is induced by the antianabolic action of these steroids which leads to liberation of nitrogen, potassium and phosphate from intracellular sources. Whereas all of the foregoing electrolyte changes may be observed following large doses of the 11 oxygenated corticoids, only part of the pattern is exhibited by desoxycorticosterone which has no oxygen atom at carbon 11 and which lacks an antianabolic action and an effect on glycogen synthesis. Removal of the adrenals is followed by sodium chloride and water loss, potassium retention, dehydration and circulatory collapse.

**Regulation of Water Balance** Water retention is observed following corticoid administration. This appears to be largely a reflection of sodium retention. Aldosterone favors an increase in extracellular sodium chloride and water. The 11,17 oxygenated corticoids, hydrocortisone and cortisone appear to exert a regulatory effect on intracellular water, facilitating water loss from cells in the presence of excessive cellular hydration and increasing the water content of dehydrated cells. Although the mechanism of interaction is not known it is generally accepted that the 11,17 oxygenated corticoids antagonize the physiological effects of the posterior pituitary antidiuretic hormone.

**Regulation of the Metabolism of Carbohydrate, Protein and Fat** The 11 oxygenated corticoids, particularly hydrocortisone and cortisone, have an anti-insulin effect. An antianabolic effect leads to increased gluconeogenesis from protein. The role of the 11-oxygenated corticoids in fat metabolism is not clear. It would appear that there is increased mobilization and utilization of fat which is not accompanied

by appreciable ketosis. The net overall effect of these adrenal steroids is increased gluconeogenesis from protein and possibly fat.

**Androgenic Function** The development of axillary hair in the male and female and of pubic hair in the female is dependent on the presence of the adrenal cortex. The adrenal androgens also possess a protein anabolic effect. This effect is most dramatically seen in the rapid growth rate of the prepubertal child with the adrenogenital syndrome.

**Regulation of Hematopoiesis and Tissue Reactivity** Only the 11,17 oxygenated corticoids, hydrocortisone and cortisone, exert significant hematological effects. These consist of an eosinopenia in all probability due to increased peripheral destruction, a lymphopenia due to increased lysis of both fixed and circulating lymphocytes, a neutrophilia and a tendency to polycythemia. With large doses of hydrocortisone or cortisone the reactivity of mesenchymal tissues to injury, irritants and foreign proteins (including microorganisms) may be greatly inhibited. As a result of this inhibitory effect on both fixed and mobile cellular defenses, inflammation is reduced but resistance to injury and infection may be seriously impaired.

**Control of Pigmentation** Primary adrenal cortical insufficiency is accompanied by an increased deposition of melanin in the skin. Following bilateral adrenalectomy this may be inhibited by the daily administration of hydrocortisone or cortisone. Desoxycorticosterone is ineffective in this regard. The absence of pigmentation in most cases of secondary adrenal insufficiency indicates that an intact anterior pituitary is necessary for this phenomenon to occur. There is evidence to suggest that in the absence of the adrenal cortex there is an increased secretion of a melanophore stimulating substance from the anterior pituitary gland.

**Effects on the Gastrointestinal Tract** Hydrocortisone and cortisone increase the secretion of hydrochloric acid and pepsin by the stomach and of the pancreatic enzymes as well. These steroids also appear to facilitate the absorption of fat from the intestinal tract.

#### ADRENOCORTICAL HORMONE AND CORTICOTROPIC PREPARATIONS AVAILABLE FOR CLINICAL USE

**1 Hydrocortisone** This hormone is available as the free alcohol in ampules containing 100 mg in 20 ml of 50 per cent ethyl alcohol for addition to intravenous

surgical operation is imposed the adrenal cortex may not respond adequately enough and a state of relative adrenal insufficiency may ensue. This may occur during the period of ACTH or cortisone administration or following the discontinuance of hormone therapy before the responsiveness of the pituitary-adrenal cortical axis has returned to normal. An adrenal crisis which may arise under these circumstances must be anticipated and supplementary hydrocortisone or cortisone administered until the period of stress has ended.

### CHRONIC ADRENAL CORTICAL INSUFFICIENCY

#### PRIMARY FAILURE (ADDISON'S DISEASE)

**Incidence and Etiology** True Addison's disease is a relatively rare condition the incidence approximating one case per 100,000 population. There are two major causes of this condition: fibrocasseous tuberculosis of the adrenal gland and an idiopathic process leading to bilateral adrenal cortical atrophy. In earlier reports the incidence of tuberculosis of the adrenal glands as a cause of Addison's disease was as high as 80 to 90 per cent. More recently the incidence of tuberculosis has diminished and approximately 50 per cent of cases are nontuberculous in origin. In a small percentage of patients, other lesions may be encountered such as bilateral tumor metastases, leukemic infiltration, amyloidosis,

hemochromatosis and histoplasmosis.

**Clinical Picture** The onset of the disease is usually insidious. Occasionally, however, the first evidence of adrenal failure may be the development of crisis precipitated by an acute infection or a surgical operation. The predominant symptoms are asthenia, easy fatigability, weight loss, increased pigmentation of the skin and mucous membranes, gastrointestinal complaints including anorexia, nausea, vomiting, diarrhea, and abdominal pain, and episodes suggestive of hypoglycemia. Increased irritability, nervousness, emotional instability, and periods of depression and negativism are not uncommon. Pigmentation usually appears early and is the most striking physical evidence of the disease. It usually presents itself as a diffuse tanning with increased pigmentation over pressure points such as the knees, elbows, and knuckles. There may be bluish black pigmentation of the mucous membranes and multiple black freckles over the body. Not infrequently vitiliginous areas or "leukoderma" may be noted. Most patients with Addison's disease have hypotension and a small heart. Secondary sex characteristics are usually little affected except for the reduction of the growth of axillary and body hair. The menstrual cycle and gonadal function are ordinarily remarkably well maintained.

**Laboratory Findings** There is a normochromic, normocytic anemia which be-

FIG. 83 Adrenal responses to intravenous ACTH

2 Penicillin is given by intramuscular injection in a minimal dosage of 400 000 units every six hours

3 If shock is profound or if hypotension persists Neo Syneprhine may be injected subcutaneously in a dose of 0.3 to 0.5 mg every one to two hours or 5 to 10 mg may be added to the intravenous infusion and the rate adjusted to maintain blood pressure at normal levels. Infusions of norepinephrine may also be employed to maintain the blood pressure. In the presence of extreme persistent shock it may be necessary to administer a transfusion of whole blood or concentrated serum albumin. Since the sodium retaining effect of intravenously administered hydrocortisone is marked it is usually not necessary to give desoxycorticosterone during the acute phase of adrenal crisis unless the hypotension is refractory to other measures. In the latter situation 10 to 20 mg of the hormone may be injected intramuscularly initially and 2.5 to 5.0 mg per day thereafter.

**Adrenal Hemorrhage** The causes and manifestations of massive bilateral adrenal hemorrhage vary with age. In the newborn infant adrenal hemorrhage may occur during a prolonged and difficult labor especially when asphyxia and traumatic resuscitation procedures are involved. In older children and adults adrenal apoplexy is usually associated with overwhelming sepsis (Waterhouse-Friderichsen syndrome). Meningococcus has been the causative organism in approximately 75 per cent of cases; other organisms have been the staphylococcus, streptococcus and pneumococcus. In a few adult cases adrenal hemorrhage has occurred as a result of anticoagulant overdosage.

Pathologically there is extensive bilateral adrenal hemorrhage which may occasionally rupture through the capsule of the adrenal into the peritoneal cavity. In those cases associated with a fulminating sepsis a widespread capillary and arteriolar necrosis is frequently observed. Frank meningitis is rarely seen.

Acute adrenal insufficiency at birth produces the characteristic picture of acute shock. Hemorrhagic manifestations are usually absent although in some cases a retroperitoneal mass may be palpated. Later in life when the disease is associated with an overwhelming septicemia there are extensive cutaneous petechiae and purpura. Early symptoms in these cases are increased irritability, nausea, vomiting, abdominal pain and headache. Shortly after

the onset of the disease a petechial rash appears which progresses to form a diffuse confluent purpuric eruption. Fever is present early and the temperature may rise to extreme levels. Intense cyanosis develops and finally circulatory collapse ensues. Death usually occurs within twenty-four to forty-eight hours after the onset of symptoms. As blood cultures are not always positive specific therapy should not await the report of bacterial growth. In some cases the meningococcus can be seen on a Gram stain of fluid obtained from carefully punctured petechial spots.

The specific diagnosis of adrenal insufficiency under these circumstances is difficult to establish. Blood steroid analysis provides the most reliable method in the acute case. Since the emergency is critical blood should be withdrawn for hormone determination and treatment for adrenal crisis instituted empirically until the results of the chemical analysis are known. Eosinopenia favors but does not prove acute adrenal insufficiency.

Treatment is similar to that outlined under Adrenal Crisis. Control of the infection is of course absolutely essential. Although formerly the Waterhouse-Friderichsen syndrome uniformly fatal in recent years several instances of recovery have been reported. It should be emphasized however that meningococcemia with purpuric rash may be associated with circulatory collapse in the absence of adrenal hemorrhage and without pathological evidence of acute adrenal cortical insufficiency.

**Acute Adrenal Insufficiency Associated with Surgery of the Adrenal Gland** This condition may occur following bilateral adrenalectomy or the removal of a unilateral adrenal cortical tumor which is associated with atrophy of the contralateral gland. Adrenal insufficiency should of course be anticipated under these conditions and adrenal cortical hormone replacement therapy instituted during and after operation as described in the section on the Treatment of Cushing's Syndrome (see table p. 740).

**Acute Adrenal Insufficiency Associated with ACTH or Cortisone Therapy** The commonest cause of acute adrenal cortical insufficiency is that which occurs in association with prolonged ACTH or cortisone administration. Here there is a diminished reactivity of the pituitary-adrenal cortical system due to pituitary inhibition in the case of ACTH administration and to both pituitary and adrenal cortical inhibition in the cases of cortisone treatment. When the stress of a severe medical illness or a

per day Each of these hormones is best given in divided doses at 8 A.M. and 3 P.M. Similar doses of cortisone and hydrocortisone when given daily to patients with Addison's disease and active tuberculosis do not appear to promote the spread of the infectious process.

During periods of intercurrent illness it is essential that the dose of cortisone be increased to a level of 75 to 100 mg per day. If the administration of the hormone by the oral route is not possible the aqueous suspension of cortisone acetate may be given intramuscularly in equivalent doses. Patients with Addison's disease who undergo surgery should be adequately prepared with supplementary hormone. It is recommended that for major surgery in Addisonian patients a therapeutic program similar to that described for patients undergoing adrenal surgery for Cushing's syndrome should be instituted (see table p 740).

Unfortunately the amounts of cortisone or hydrocortisone required to restore to normal the metabolism of carbohydrate, protein and fat are too small to assure normal electrolyte and water balance. Thus adequate hydration and blood pressure stabilization require either the use of 10 to 15 gm of supplementary sodium chloride per day or in the vast majority of cases the use of small amounts of desoxycorticosterone acetate (DCA) with a normal sodium and potassium intake. It is customary to give 2.5 to 5.0 mg of desoxycorticosterone acetate in oil once daily intramuscularly or 25 to 75 mg of long acting trimethylacetate ester intramuscularly once monthly or 0.1 to 0.5 mg of fluorohydrocortisone once daily by mouth. Body weight, blood pressure, heart size and serum potassium are followed the dose being adjusted to bring these measurements within normal limits. In elderly patients or in the presence of hypertension, edema or cardiac enlargement all salt retaining steroid hormone therapy should be discontinued and the patient's mineral requirement should be regulated by diet alone.

Because of the relatively small doses of cortisone employed in maintenance therapy undesirable effects such as are encountered in the treatment of collagen diseases are rarely seen. Gastric irritation occasionally occurs in patients taking cortisone acetate by mouth. This is overcome in most instances by giving the hormone during meals. Increased excitability and sleeplessness are only rarely encountered if the last dose of cortisone is given no

later than 4 P.M. Psychotic reactions are quite uncommon but occasionally occur even at low dosages. This demands reduction in dosage until the patient's psyche becomes stable. In view of this side effect it is advisable to start therapy with a small dose (12.5 mg per day) of the hormone.

Patients with Addison's disease and those who have undergone bilateral adrenalectomy should carry a card with them at all times bearing the doctor's name, telephone number and address, the patient's disease, his name and address and that of the nearest of kin. In addition the following sentence should be written: "In the event of illness administer 25 mg of cortisone acetate every six hours by mouth unless the patient is unconscious when 200 mg of the hormone should be given by intramuscular injection."

**Prognosis.** In the absence of active tuberculosis the outlook is good with modern substitution therapy. On DCA alone five year survival in a large group of patients was increased from 20 per cent in the salt treatment era to 50 per cent. Further improvement is to be anticipated now that cortisone and hydrocortisone are available.

#### CHRONIC ADRENAL CORTICAL INSUFFICIENCY SECONDARY TO PITUITARY FAILURE

This condition is due to an anterior pituitary insufficiency of ACTH. It differs from primary adrenal insufficiency (Addison's disease) in that the electrolyte disturbance is usually less marked, the susceptibility to hypoglycemia is greater and pigmentation is minimal or absent. Associated deficiencies of gonadal and thyroid function are ordinarily present and in many patients dominate the clinical picture. The response to ACTH is typically delayed in proportion to the degree of secondary adrenal cortical atrophy (Fig 83). Treatment involves the use of cortisone or hydrocortisone as described above for Addison's disease. Desoxycorticosterone is administered if there is a significant tendency towards salt loss. In addition thyroid extract and testosterone are employed as indicated.

#### CHRONIC ADRENAL CORTICAL INSUFFICIENCY SECONDARY TO ADRENALECTOMY

Patients who have undergone total and in many instances subtotal adrenalectomy require adrenal cortical hormone replacement therapy similar to that described for Addison's disease. These patients however are particularly susceptible to the effects of cortisone deprivation. Moreover they may tolerate larger quantities of cortisone than

comes accentuated when rehydration is achieved. There is a tendency to lymphocytosis and moderate eosinophilia. In severe deficiency low serum sodium and chloride and a high serum potassium are observed. Hypoglycemia may occur during extended fasting or following high carbohydrate loads. Urinary 17 ketosteroid excretion is diminished in the male and may be virtually absent in the female. The level of urinary 17 hydroxycorticoids is generally below 1 mg per day. Although 20 to 25 per cent of patients reveal adrenal calcification on roentgenographic examination this finding is not pathognomonic of adrenal insufficiency. The basal metabolic rate is often between minus 10 and minus 20 per cent. The blood plasma volume is reduced. The electrocardiogram characteristically shows a low voltage and there is a decreased frequency of the waves on the electroencephalogram.

**Diagnosis** The most definitive diagnostic procedure is the demonstration of a lack of adrenal cortical response to the administration of pituitary corticotrophin (ACTH). In the 8 hour intravenous ACTH test 25 USP units of the hormone are infused intravenously in 500 ml of 5 per cent dextrose in saline over an 8 hour period on each of three successive days. Determinations of urinary 17 ketosteroids and 17 hydroxycorticoids are carried out on twenty four hour collections on a control day and on each of the three days during ACTH administration. Blood is taken for an eosinophil count at the beginning and end of each infusion. Under these circumstances a normal subject will exhibit an increase of 8 to 16 mg per day in the excretion of 17 hydroxycorticoids and 4 to 11 mg per day in the excretion of 17 ketosteroids while patients with Addison's disease will show virtually no response. Normal subjects will respond with an eosinopenia of 80 to 90 per cent whereas Addisonian patients show little or no change. Patients with hypopituitarism and ACTH insufficiency exhibit varying responses depending upon the degree of adrenal cortical involution.

An alternative method of testing adrenal cortical response consists in the intramuscular injection of 40 units of ACTH gel twice daily over a two day period. Urinary 17 ketosteroids and 17 hydroxycorticoids are determined on a control day and on each of the days of ACTH administration. Eosinophil counts are checked before each morning injection. Results are similar to those obtained with the intravenous ACTH

test. Occasionally a false negative response is observed when extravascular inactivation of ACTH prevents the hormone from reaching the adrenal cortex. Thus with a negative response to the injection of ACTH gel one should always resort to intravenous administration of the hormone.

The four hour ACTH test may be of value as a rapid screening procedure. In this test the level of circulating eosinophils is determined before and four hours after the intramuscular injection of 25 USP units of ACTH in aqueous solution. A fall in circulating eosinophils exceeding 50 per cent of the initial value makes adrenal insufficiency highly unlikely. A fall of less than 50 per cent may be due to adrenal cortical insufficiency but can also be caused by inadequate adrenal stimulation due to extravascular destruction of ACTH. In the latter event the more definitive ACTH tests described above must be employed.

The ACTH test may also be used in conjunction with blood steroid response changes in blood steroid level being observed at the beginning and end of four or eight hour infusion of 25 units of ACTH. This method has not been widely used as the twenty four hour urinary measurement but is useful in those situations in which accurate urine collections cannot be made.

There is no justification today for the use of the nonspecific diagnostic tests such as water excretion, salt deprivation and insulin and glucose tolerances if hormonal analyses following ACTH administration can be obtained.

**Treatment** As a result of the remarkable advances in recent years in the preparation of crystalline adrenal steroids, highly effective replacement therapy is now possible for patients with Addison's disease. The prognosis of such patients has been particularly improved since the advent of cortisone. The administration of this hormone leads to a restoration of appetite, muscular strength and body weight and a general feeling of well being. The anemia is corrected, the tendency to hypoglycemia is reduced, the electrocardiogram and electroencephalogram return toward normal, the capacity to excrete an ingested water load improves, pigmentation is lightened and the capacity to withstand the stress of intercurrent infection and trauma is greatly enhanced. Adequate maintenance therapy is provided by an average daily dose of cortisone of 25 to 37.5 mg by mouth. Alternatively hydrocortisone may be administered in a dose of 20 to 30 mg by mouth.

ceived long term cortisone therapy In the presence of bilateral hyperplasia basophil adenoma is frequently found These tumors are small and enlargement of the sella turcica is exceedingly rare

The most striking generalized pathological change in Cushing's syndrome is protein depletion There is osteoporosis and general muscle wasting The blood vessels are fragile and frequently show changes secondary to hypertension Widespread fatty degeneration is common The kidneys reveal nephrosclerosis and calcinosis The pancreas may show fatty necrosis and islet cell hyperplasia

**Clinical Picture** The clinical picture of Cushing's syndrome is essentially the expression of an excessive secretion of hydrocortisone-like hormones (Fig 84) The most striking feature is protein depletion which is evident in muscle skin blood vessels and bone Marked weakness is associated with diminution of muscle mass

Fragility of the skin and blood vessels is evidence by depressed purple striae over the abdomen thighs and upper arms and increased susceptibility to bruises and ecchymoses Osteoporosis leads to backache and dorsal kyphosis and compression fractures of the vertebrae are not uncommon

Increased gluconeogenesis from protein and possibly fat leads to a diminished carbohydrate tolerance and occasionally diabetes

There is a striking redistribution of fat with the obesity confined to the face neck and trunk The combination of supraclavicular fat pads combined with dorsal kyphosis give rise to the "buffalo hump" while the facial obesity is seen as the typical "moon face"

Facial plethora hypertension and peripheral edema are common Lability of mood is usually present and occasionally there may be an overt psychosis

Female patients with Cushing's syn

FIG 84 Classic appearance of patient suffering from Cushing's syndrome due to bilateral adrenal hyperplasia Note (a) the moon facies the truncal obesity and (c) the cutaneous striae over the lower abdomen and hips (R H Williams Textbook of Endocrinology)

patients with Addison's disease and often only attain an optimal state of well being on doses of 37.5 to 50 mg per day. In addition their requirement for desoxycorticosterone is considerably more variable than is the case for patients with Addison's disease.

#### CHRONIC ADRENAL INSUFFICIENCY ASSOCIATED WITH CONGENITAL ADRENAL CORTICAL HYPERPLASIA

Congenital bilateral adrenal cortical hyperplasia causes pseudohermaphroditism in females and sexual precocity in males. Acute adrenal insufficiency may occur in these instances, especially in males. It is characterized by salt loss, dehydration and eventually circulatory collapse. More commonly the illness may pursue a subacute course marked by periods of dehydration, rapid weight loss, vomiting, diarrhea and abdominal pain, usually in association with intercurrent infections. Hypoglycemia ordinarily does not occur. Treatment of acute adrenal insufficiency in these patients is the same as in other types of adrenal crisis. The use of cortisone in maintenance therapy is discussed below in the section of the adrenogenital syndrome. When cortisone alone does not control salt loss, desoxycorticosterone must be added to the therapeutic regimen.

#### HYPERFUNCTION OF THE ADRENAL CORTEX

The clinical picture of hyperadrenocorticism extends in a broad spectrum from Cushing's syndrome at the one end to the adrenogenital syndrome at the other. Cushing's syndrome is the expression of an excessive adrenocortical secretion of the 11-17 oxygenated corticoids, hydrocortisone and cortisone, while the adrenogenital syndrome is the manifestation of an increased secretion of androgens from the adrenal cortex. Between these two extremes there are many patients who present manifestations of each syndrome to a varying degree. Rarely adrenal cortical hyperfunction may be associated with feminization in the male. Twelve such cases have been reported and all have been due to estrogen-producing malignant adrenal cortical tumors.

#### CUSHING'S SYNDROME

This syndrome was first clearly recognized by Harvey Cushing in 1932. While admitting that certain of the cases were due to primary adrenal disease, adenoma or carcinoma, Cushing believed that in those patients with a pituitary basophil

adenoma and bilateral adrenal cortical hyperplasia ("Cushing's disease") the disturbance rested in the anterior pituitary.

**Etiology.** Cushing's syndrome represents the effects of a long continued excessive secretion of 11-17 oxygenated corticoids, hydrocortisone and cortisone, by the adrenal cortex. The adrenal lesion may be adenoma, carcinoma or bilateral hyperplasia, rarely unilateral hyperplasia, may be found. Much more rarely a tumor in aberrant adrenal cortical tissue (e.g., ovary) may be seen in association with bilateral atrophy of the adrenal glands. When congenital Cushing's syndrome is almost always associated with bilateral adrenal hyperplasia. When the disease has its onset during the prepubertal period the adrenal lesion is usually a malignant tumor. In 60 per cent of adult cases bilateral adrenal cortical hyperplasia is found in 30 per cent an adenoma or a carcinoma, while in 10 per cent of cases the adrenal cortices appear normal. In many of the patients with normal or hyperplastic adrenals there is a basophil adenoma in the anterior pituitary; in these cases the primary lesion is believed to be in the pituitary from which there is increased secretion of ACTH.

**Incidence.** Cushing's syndrome is a rare disorder which occurs much more frequently in the female than in the male. Actively secreting adrenal cortical adenomas are practically confined to the female. The incidence of the disease is at its peak in the third and fourth decade. The syndrome appears to occur particularly frequently following pregnancy.

**Pathology.** Bilateral hyperplasia is characterized by symmetrical enlargement of the cortex with increased convolution of the surface. Not infrequently a few hyperplastic nodules are present. Microscopically the hyperplasia is particularly marked in the zona fasciculata. The single and rarely multiple adenomas are well demarcated and surrounded by a narrow rim of atrophied cortical tissue. Carcinoma of the adrenal cortex is often highly malignant with spread of the tumor usually occurring by vein. The liver is a frequent site of metastases. When a unilateral adenoma or carcinoma is present there is atrophy of the contralateral adrenal cortex due to suppression of the output of ACTH from the anterior pituitary. Hyalinization of the basophil cells (Crooke's changes) of the anterior pituitary is invariably present in Cushing's syndrome. Similar changes have been observed in patients who have re-

phils are indications that therapy has been effective

In more seriously ill patients (particularly those with marked mental changes or extensive protein depletion *e.g.* severe osteoporosis with fractures) or in those early cases which have failed to respond to roentgen therapy bilateral subtotal or total adrenalectomy is recommended. Bilateral total adrenalectomy is preferred to prevent the recurrence of hyperadrenocorticism.

Adrenal cortical hormone therapy is routinely instituted prior to operation and continued during and after surgery as outlined in the accompanying table. In the presence of hypotension Neo-Synephrine or norepinephrine should be given intravenously at a rate sufficient to maintain the blood pressure at normal levels.

Patients who have undergone complete bilateral adrenalectomy must be treated in the same manner as are those with Addison's disease. Although the availability of hydrocortisone and cortisone has greatly facilitated adrenalectomy in patients with Cushing's syndrome it must be emphasized strongly that these patients are extremely fragile and particularly prone to postoperative complications.

**Unilateral Adrenal Cortical Adenoma or Carcinoma.** When Cushing's syndrome is due to an adrenal cortical tumor surgical removal is necessary. Because the uninvolvement of the contralateral adrenal cortex is atrophied owing to suppression of ACTH secretion from the anterior pituitary, adrenal cortical hormone therapy must be instituted as described for patients undergoing bilateral total adrenalectomy for hyperplasia. Within two weeks after surgery the status of the contralateral adrenal cortex is evaluated by the determination of urinary 17-hydroxycorticoids during ACTH administration and rapid tapering of cortisone dosage over a five-day period. The ACTH is given daily either in a dose of 20 USP units by intravenous infusion over an eight-hour period or in doses of 80 units of the gel preparation in a single intramuscular injection. A gradual rise in the level of urinary 17-hydroxycorticoids during this period indicates that the remaining adrenal gland is functioning adequately. The ACTH dosage is then very gradually tapered to allow the inhibited anterior pituitary to return to normal. Occasionally irreversible atrophy of the contralateral gland occurs and permanent substitution therapy as for Addison's disease is required.

## ADRENOGENITAL SYNDROME AND ADRENAL VIRILISM

Apart a French physician introduced the term adrenal virilism in 1910 to designate a syndrome of masculinization in women which he related to alterations in adrenal cortical function. Its biological counterpart feminization in the male has since been recognized as an extremely rare condition.

**Etiology.** The manifestations of adrenal virilism are due to an increased secretion of androgens from the adrenal cortex. The adrenal lesion may be bilateral hyperplasia, adenoma or carcinoma. Adrenal virilism which is evident at birth is almost invariably due to bilateral hyperplasia. When the disease has its onset in later life the lesion is usually a tumor, more frequently a carcinoma. It is not certain at the present time whether those cases with bilateral hyperplasia are due to a primary anterior pituitary disturbance with an increased secretion of ACTH.

**Pathology.** While it is difficult to correlate cytological changes in the adrenal cortex with the type of endocrine disturbance produced, it is not uncommon to find in cases of virilization due to bilateral adrenal cortical hyperplasia that the overgrowth is primarily in the zona reticularis. The virilizing tumors are frequently highly malignant and metastasize chiefly to the liver and lungs.

**Clinical Picture.** As a result of their virilizing properties an increased secretion of adrenal androgens may lead to female pseudohermaphroditism at birth, precocious puberty in the preadolescent male and heterosexual development in the preadolescent and adolescent female. In addition to their androgenicity these hormones possess a protein anabolic effect. Thus while patients with Cushing's syndrome present evidence of protein depletion, those with the adrenogenital syndrome show signs of protein conservation *e.g.* increased rate of growth in the prepubertal child and increased muscle mass in the adult. Heterosexual development in the young female is characterized by hirsutism, deepening of the voice, absence of breast development, enlargement of the clitoris and amenorrhea. It must be emphasized that when adrenal virilism is due to bilateral hyperplasia, particularly the congenital variety, the symptoms and signs of Addison's disease may be present. Such patients are particularly prone to develop evidence of salt deficiency.

## Hormone Therapy Following Complete Adrenalectomy

## Preoperatively

Cortisone acetate 100 mg I M  
12 hrs and 2 hrs preop

## During Operation

Hydrocortisone 100 mg I V  
Repeated ■ and 12 hrs postop  
Cortisone acetate 50 mg I M q 6 hr

## Postoperatively

Day 1—cortisone acetate 50 mg I M q 6 hr  
Day 2 3—50 mg I M q 8 hr  
Day 4 5 6 7\*—50 mg P O q 12 hr  
Day 8 9 10—25 mg P O q 8 hr  
Thereafter taper cortisone acetate P O slowly to maintenance needs \*\*

\* Salt retaining hormone (desoxycorticosterone or fluorohydrocortisone) may be required after day 7

\*\* In patients with severe Cushing's disease and excreting large quantities of 17 hydroxycorticoids into urine it is essential to reduce the cortisone dosage somewhat more slowly than ■ shown in the table

drome may show signs of masculinization with hirsutism acne deepening of the voice amenorrhea and enlargement of the clitoris In these cases there is probably an increased secretion of androgens as well as hydrocortisone like hormones by the adrenal cortex

The clinical course ■ characterized by progressive weakness increased susceptibility to infection the symptoms of which are often masked and the appearance of fractures of the spine Death occurs from vascular accidents intercurrent infection or diabetic coma

**Diagnosis** The combination of marked protein depletion the typical fat distribution and a diminished carbohydrate tolerance strongly favors the diagnosis of Cushing's syndrome Sudden onset suggests an adrenal cortical adenoma or carcinoma an insidious onset favors bilateral hyperplasia

**Definitive diagnosis** of Cushing's syndrome requires the determination of urinary 17 ketosteroids and 17 hydroxycorticoids The urinary excretion of 17 hydroxycorticoids ■ almost invariably increased In general the level of 17 ketosteroids is lower than normal in the presence of an adenoma normal or slightly elevated with bilateral hyperplasia and above 30 mg per day when the lesion ■ a carcinoma of the adrenal cortex Differentiation of these lesions may be considerably helped by study of the patient's response to an eight hour intravenous infusion of ACTH Patients with bilateral hyperplasia tend to show a hyperactive response as measured by rises in urinary 17 ketosteroids and 17 hydroxycorticoids When the lesion is ■ carcinoma usually no response is observed

In the presence of an elevated level of urinary 17 ketosteroids further help in the differentiation of tumor and bilateral hyperplasia of the adrenal cortex may be obtained by following the urinary 17 ketosteroid excretion during the administration

of 9 alpha fluorohydrocortisone 5 to 10 mg daily over a six-day period Patients with bilateral hyperplasia usually show a fall in 17 ketosteroid excretion while those with carcinoma may show no change

Diagnostically helpful laboratory findings are an eosinophil count below 50 per cu mm lymphopenia neutrophilia and polycythemia Glycosuria with diminished carbohydrate tolerance is of frequent occurrence occasionally frank diabetes mellitus may be present In a small number of cases there is a hypokalemic hypochloremic alkalosis Roentgenogram of the sella turcica is almost invariably normal Films of the skull and spine show osteoporosis and compression fractures of the vertebrae may be found An abdominal film may outline an adrenal mass while intravenous pyelograms may reveal depression of the renal shadow Retroperitoneal pneumograms may be of value in the detection of an adrenal mass and the differentiation of adenoma or carcinoma from bilateral hyperplasia

**Treatment** Whatever the plan for specific therapy it is well to administer potassium chloride 6 gm per day by mouth in the presence of a hypokalemic hypochloremic alkalosis and to combat the protein depletion by the administration of testosterone propionate 25 mg daily by intramuscular injection

**Bilateral Adrenal Cortical Hyperplasia** When all efforts to detect the presence of an adrenal cortical tumor have failed and bilateral hyperplasia is suspected *pituitary irradiation* may be instituted in those early cases which show minimal signs of protein depletion and only mild psychic involvement A minimum dose of 3000 r should be delivered to the gland Improvement occurs in approximately one quarter of these cases within three months following the commencement of therapy A fall in the titer of urinary 17 hydroxycorticoids and a rise in the level of circulating eosino-

distinguish them histologically from adrenal tumors associated with other syndromes of adrenal hyperfunction. Renal arteriosclerosis has been observed as well as hydropic degeneration of renal tubules and degenerative changes in skeletal muscle. It has been postulated that the severe potassium depletion observed in these patients is responsible for many of the secondary changes in vital tissues.

**Physiological Considerations** In contrast to the secretion of corticosterone, hydrocortisone and the adrenal androgenic steroids, aldosterone secretion is not dependent upon ACTH. Thus normal levels of aldosterone in the urine may be observed in patients with Simmonds disease or following hypophysectomy. Under special circumstances it appears that the secretion of aldosterone may be enhanced by ACTH administration but certainly the baseline secretion of this hormone is not dependent upon ACTH. The inability to detect aldosterone in the peripheral blood of patients must make one cautious in the interpretation of the urinary changes in aldosterone level. To date both the biological assay method and the physicochemical method of Neher and Wettstein are tedious, relatively nonspecific and of limited accuracy. It can be readily shown that aldosterone excretion in the urine and presumably aldosterone secretion may be modified rapidly by changes in body hydration and by alteration in sodium or potassium balance. Sodium deprivation rapidly leads to increased aldosterone urinary levels. This also is observed following the administration of large doses of potassium.

**Clinical Signs and Symptoms** Periodic episodes of muscular weakness dominate the clinical picture. These may progress to actual paralysis. Muscles of the trunk and extremities are more likely to be affected. Those innervated by the cranial nerves are often spared. The attacks may be transient or may last for hours to weeks. Tetany may be observed. Polyuria and polydipsia are prominent symptoms. Hypertension, hypertensive retinopathy and cardiac enlargement have been present in the majority of instances. Edema notably is absent.

Laboratory findings include a decreased serum potassium, elevated carbon dioxide content, depressed serum chloride, normal or elevated serum sodium level and an elevated pH of the serum and urine. These changes are characteristic of the so-called hypokalemic metabolic alkalosis. Urinary sodium and potassium concentrations are

normal. Abnormalities in the electrocardiogram indicative of potassium depletion are almost always present. The urinary 17-keto and 17-hydroxy steroid excretion is usually normal, whereas urinary aldosterone values are almost always increased.

**Diagnosis** The diagnosis should be suspected in any patient presenting (1) unexplained episodes of muscular weakness, (2) tetany with a normal serum calcium, (3) diabetes insipidus-like syndrome refractory to Pitressin, (4) unexplained hypokalemic metabolic alkalosis, (5) unexplained hypokalemic changes in the cardiogram of a hypertensive nonedematous patient. All patients with hypertension and hypokalemia should be checked for possible hyperaldosteronism.

**Differential Diagnosis** (1) Familial periodic paralysis is usually an hereditary disorder. It occurs in young persons. Between attacks the serum potassium level and muscle function are usually quite normal. Obviously hyperaldosteronism may mask as periodic paralysis.

(2) Potassium-losing nephritis may be due to long-standing primary renal disease. The presence of marked impairment in renal function such as azotemia suggests primary renal disease rather than the nephropathic changes induced by hyperaldosteronism. Undoubtedly some of the cases reported earlier in the literature as cases of "potassium-losing nephritis" may have been undiagnosed cases of primary hyperaldosteronism.

(3) Tetany due to parathyroid deficiency and hypovitaminosis D can be distinguished by the low serum calcium level. In primary aldosteronism tetany is associated with an alkalosis, low serum potassium and normal calcium and phosphorus levels.

(4) *Secondary hyperaldosteronism* is represented by a group of patients with cardiac renal or hepatic edema in whom elevated levels of aldosterone may be demonstrated. These patients characteristically excrete a urine of low sodium concentration. The pathogenetic significance of the hyperaldosteronism may be investigated by the use of substances such as amphenone which temporarily inhibit the secretion of aldosterone.

**Treatment** The only cure at present for hyperaldosteronism is the removal of the adrenal tumor or bilateral adrenalectomy if the process is not localized. Since aldosterone is not an effective inhibitor of ACTH secretion, the removal of a tumor in one adrenal does not ordinarily give rise to signs of adrenal insufficiency. Since how

At all ages the psychological and social problems associated with this disease must be given careful consideration

Invariably in this condition there is an increased excretion of urinary 17 ketosteroids. High values (50 mg per day or more) with an increased proportion of the beta fraction (largely dehydroisoandrosterone) in combination with high levels of urinary estrogens are strongly suggestive of carcinoma of the adrenal cortex as opposed to hyperplasia or adenoma. In the presence of congenital adrenocortical hyperplasia the blood ACTH level is high while urinary and blood levels of 17 hydroxycorticoids are low. The response of the latter to ACTH is subnormal or absent. The presence of a tumor may be detected by means of an abdominal film, intravenous pyelography or retroperitoneal pneumography.

**Differential Diagnosis.** Sexual precocity in the prepubertal male may be constitutional owing to a pineal tumor to lesions in the hypothalamus or to a Leydig cell tumor of the testes as well as to an adrenal cortical lesion. Heterosexual development in the prepubertal or adult female may be caused by a lesion in either the adrenal cortex or the ovary. The ovarian lesions include arrhenoblastoma, Leydig cell tumor, adrenal rests, luteoma and polycystic disease (Stein-Leventhal syndrome). Differentiation between ovarian and adrenal lesions as the cause of the virilizing syndrome may be helped by following the level of urinary 17 ketosteroids during the administration of fluorohydrocortisone in a dose of 5 to 10 mg daily for five to ten days. Dietary sodium should be restricted. Should a dramatic fall in urinary 17 ketosteroid excretion occur the causal lesion is presumed to be bilateral adrenal cortical hyperplasia. When persistent depression of the urinary 17 ketosteroid level is not observed it is presumed that the lesion is either an adrenal cortical tumor or ovarian disease. In this instance the relatively simple operation of pelvic laparotomy is first performed. In the absence of a responsible ovarian lesion the adrenals are then explored.

**Treatment.** Treatment of virilizing adrenal cortical tumor is surgical removal. In a few cases atrophy of the uninvolved contralateral gland has been found and it is therefore wise in all instances to institute adrenal cortical hormone therapy as described previously for operation on patients with Cushing's syndrome due to tumor. When the lesion is a carcinoma with wide

spread metastases postoperative x-ray therapy is advised but it is usually of little value.

When adrenal virilism is associated with bilateral hyperplasia a congenital condition which occasionally goes unnoticed until adulthood the treatment of choice is cortisone suppression of adrenal androgen secretion. Therapy is usually initiated with intramuscularly administered hormone at a dosage level of 50 mg per day for older children and 25 mg per day for younger children and infants. Thereafter the dose of cortisone should be gradually tapered to that level which gives reasonable suppression of adrenal androgen secretion with minimal untoward side effects of the latter. A diminution in the rate of growth is particularly to be watched for. For older children maintenance doses of 50 mg of cortisone every other day by intramuscular injection are usually optimal whereas in infants and younger children smaller doses may be quite adequate. The amount of orally administered cortisone which is required for maintenance is approximately two to three times as great as that which is effective by the intramuscular route. In those cases of bilateral hyperplasia associated with adrenal insufficiency cortisone alone may not control salt loss and desoxycorticosterone must be added to the therapeutic program.

### HYPERALDOSTERONISM

The isolation in 1952 by Simpson, Tait and Bush of a potent sodium retaining factor from adrenal venous blood set the stage for the detection of the clinical syndrome hyperaldosteronism. In 1955 Conn described a patient with arterial hypertension, polyuria, hypokalemia, muscular weakness, hypochloremia and alkalosis with a high urinary output of aldosterone. Removal of an adrenal tumor was followed by amelioration of the signs and symptoms of the syndrome and the disappearance of aldosterone from the urine.

**Etiology and Pathology.** The manifestations of the syndrome appear to be due to the metabolic alterations induced by the increased secretion of aldosterone. All recorded cases have occurred in adults. In nine of these cases an adrenal tumor was found—an adenoma in eight and a carcinoma in one. In one case no tumor was discovered and the syndrome was cured following bilateral adrenalectomy. Analyses of the tumors have revealed high levels of aldosterone. No distinctive structure of these tumors has been found which would

## DISEASES OF THE SEX GLANDS

## Diseases of the Male Gonads

The two principal functions of the testis are (1) production and nutrition of spermatozoa by the seminiferous tubules and (2) secretion of androgen into the circulation by the interstitial cells of Leydig. By virtue of its hormonal secretion the testis promotes development and maintenance of the male accessory reproductive structures and masculine secondary sexual characteristics and in addition exerts a profound effect on body functions apart from those intimately concerned with reproduction.

Although there may be discordance between hormonal function and spermatogenesis as is often the case in infertility many disorders of the testis affect both processes.

## Sex Determination and Sex Differentiation

Recent studies suggest that the diploid cells of man contain 46 chromosomes composed of 44 autosomes and one pair of sex chromosomes (XX in the female and XY in the male). The X chromosome seems to contain the female determining genes and the autosomes the male genic factors. Early in the growth of the embryo unequal balance among the sex-determining genes has been postulated to govern differentiation of the bipotential embryonic gonad toward either testis or ovary. In the heterozygote male (XY) in contrast to the homozygote female (XX) the single X chromosome is insufficient to overcome the male genic balance of the autosomes. Spontaneous and experimentally produced forms of ambisexual development provide evidence that this genetic balance system of sex determination is not absolute and may be modified by various genetic, hormonal and environmental factors.

Sex differentiation takes place in three steps involving successively (1) the gonad (2) the genital ducts and (3) the urogenital sinus and external genitalia (Fig. 85).

Normally the pattern of all the sexual structures conforms to the genetic sex established in the zygote at the moment of fertilization.

**Gonadogenesis** The primordial gonad arises in the urogenital ridge from the intermediate mesoderm. Early in its development the bipotential primitive gonad (Fig. 85) is composed of two unipotential mesodermal primordia each with a distinct physiological as well as morphological capacity: (1) a cortical component consisting of the germinal epithelium and (2) a medullary component made up of the primary sex cords (derived from the germinal epithelium) and mesonephric and blastemal elements. A third constituent the primordial germ cells which appear to be bipotential arises from an extragonadal site. The cortical component can differentiate only as an ovary and the medullary component only as a testis (Fig. 85) normally the dominant element follows the genetic sex of the zygote and the recessive element retrogresses.

When the gonad destined to become a testis begins to differentiate in a male direction during the seventh to eighth week of embryonic life the cortical component involutes. Within the medulla seminiferous tubules form from the primary sex cords and anastomose with the rete testis and testicular ducts and Leydig cells develop. Leydig cells proliferate predominantly during the first half of gestation but then gradually involute persisting until shortly after birth.

**Accessory Sex Structures** Fetal castration experiments in placental mammals have thrown light on the embryogenesis of the accessory sex structures. Jost and others demonstrated that castration of male fetuses at an early critical period prevented the differentiation of male structures and led to entirely female development of ducts, urogenital sinus and external genitalia. These studies in the light of recent observations of anomalies of sex in man support the notion that a fetal testicular morphogenetic hormone is essential to pre-

ever the status of the second adrenal is not always known it is wise to give supplementary adrenal hormone therapy during and immediately following the operation i.e. 100 mg of hydrocortisone intravenously following the removal of the adrenal and 100 mg of cortisone intramuscularly at the same time. The dose of cortisone may be repeated once or twice at intervals of eight to twelve hours.

Supplementary potassium therapy i.e. potassium chloride 4 to 8 gm daily should be given preoperatively and postoperatively if tolerated. Patients with long standing hyperaldosteronism may have a serious potassium deficit in their tissues. The electrocardiogram may be more accurate than the serum potassium level in indicating ultimate tissue restoration of potassium. Failure to cure the syndrome may result in death from hypertensive cardiovascular disease. Following successful removal of the offending adrenal tissue one may anticipate a restoration toward normal of the blood pressure, cardiac size and altered blood and urine chemical values.

#### NONFUNCTIONING ADRENAL CORTICAL TUMORS

Benign nonsecretory cortical adenomas are a frequent finding at autopsy. These tumors which are rarely more than 2 to 3 cm in diameter are well circumscribed yellow masses similar in appearance to the normal adrenal cortex. They are seen more frequently in middle aged or elderly subjects and in women more often than in men.

Nonfunctioning primary adenocarcinomas are extremely rare. Unfortunately the tumor is seldom recognized until it is large enough to be palpable or until metastases

have occurred. It is often mistaken for a kidney and its true character may only be demonstrated by roentgenographic studies (pyelography, pneumography) or at operation. The tumor must be removed surgically. Pre and postoperative replacement therapy such as is essential in patients with functioning adrenal cortical tumors is not necessary in these patients.

Carcinomas of the lung and breast frequently metastasize to the adrenal glands. Patients with these tumors may occasionally die of adrenal insufficiency induced by such metastases.

FIG 86

sulfuric acid other tissues play a less important role in its metabolism. The major identifiable urinary metabolites are the 17 ketosteroids androsterone and etiocholanolone which are excreted principally as glucuronides (Fig 86). A small amount of testosterone is also transformed into and excreted as estrogen.

The testis is under the direct control of the anterior pituitary gland which secretes follicle stimulating hormone (FSH) and interstitial cell stimulating (ICSH) or luteinizing hormone (LH) both of which are glycoproteins. FSH stimulates growth of seminiferous tubules and development of spermatozoa. Luteinizing hormone induces the Leydig cells to secrete androgen and probably estrogen. It has been shown that androgens can also stimulate and maintain spermatogenesis in hypophysectomized animals under certain experimental conditions. As is true of many other endocrine glands there is a reciprocal relationship between the hypophysis and the hormonal secretion of the testis. The hypothalamus also exerts an effect on the secretion of pituitary gonadotropic hormones as evidenced in man by the association of precocious puberty or sexual infantilism with certain organic lesions of the hypothalamus.

It has long been known that doses of testosterone sufficient to reverse signs of androgen deficiency in castrated animals and men frequently fail to reduce the elevated levels of urinary gonadotropin or to reverse the castration changes in the anterior hypophysis. This fact led to the detection of a second testicular hormone namely estrogen capable in physiological doses of inhibiting the secretion of gonado-

tropin. There is also indirect evidence that the testis may secrete a third hormone ("inhibin" or X hormone). In man destructive lesions or defects involving only the seminiferous tubules are often accompanied by elevated levels of gonadotropin. However the mechanism responsible for this rise in FSH excretion remains uncertain.

## Evaluation of Testicular Function

**Clinical Assessment.** A clinical estimate of the adequacy of androgenic function is obtained by ascertaining the degree of development of the penis and scrotum, the size of the prostate, the general maturity and status of male secondary sex characters, the habitus and skeletal proportions, muscular development and potential. Although of great value this method of assessment has limitations. Once adult maturation has been attained signs of androgen deficiency are difficult to detect by clinical means even when there is complete loss of Leydig cell function in the mature male (e.g. after castration). Regression of secondary sexual characteristics is a slow and selective process. Further in addition to disease states which may alter the responsiveness of the target organs to hormone stimulation it is well recognized that there are also racial, familial and individual differences in the sensitivity of these structures. In this regard the American Indian, African Negro and some Orientals have sparse or absent facial and body hair despite normal testicular function.

**Determination of Urinary 17 Ketosteroids and Androgen.** It must be emphasized that steroids derived from the adrenal cortex comprise about 80 per cent of the total 17 ketosteroids in urine (and a significant fraction of the androgenic activity). Androsterone (an androgen) and etiocholanolone (a nonandrogenic steroid) the principal urinary metabolites of testosterone are also metabolites of 11-deoxygenated adrenocortical steroids. These facts limit the usefulness of measurement of 17 ketosteroid excretion for evaluation of Leydig cell function. Testosterone which has an hydroxyl group at carbon atom 17 is not a 17 ketosteroid (Fig 86).

The normal range of 17 ketosteroid excretion in men is 8 to 25 mg per day (mean 15 mg). Prior to puberty only small amounts of 17 ketosteroids and androgen

vent the inherent tendency of the fetus to feminize

## Chemistry and Physiology

A wealth of knowledge has firmly established the primary role of testicular hormones (1) in the development and maintenance of the male accessory sex organs—including the penis and scrotum Cowpers and preputial glands—and the secretion of semen and (2) in the development of masculine secondary sexual characters. Substances with these properties are called androgens the most potent produced by man is testosterone.

All of the properties of testicular androgens are shared by androgenic hormones derived from adrenocortical secretions. However in the castrate male the latter are insufficient to prevent eunuchism.

It has been assumed since 1935 that testosterone is the principal testicular androgen a contention borne out by the recent isolation of this steroid from human spermatic vein blood. From animal experiments in which the seminiferous tubules were destroyed without affecting the Leydig cells

it has been concluded that testicular androgen originates in the Leydig cells. Clinical signs of androgen deficiency are absent in certain testicular disorders in man associated with defective seminiferous tubules but with intact Leydig cells.

Recent studies have partially elucidated a pathway for the biosynthesis of testosterone by the testis (see section on Steroid Metabolism). The Leydig cells are capable of synthesizing testosterone from available precursors such as cholesterol and acetate by the enzymatic conversion of these compounds to progesterone and 17 hydroxyprogesterone and then to testosterone and androstenedione. There is also good evidence that the testis can convert testosterone to the aromatic steroid estradiol 17 $\beta$ . The estrogens estradiol 17 $\beta$  and estrone have been isolated from normal human testes and from testicular tumors. Although the adrenal cortex also elaborates estrogens the testis seems to be the principal source in the male. Within the testis the site of their formation is still uncertain. Both the Leydig cells and the Sertoli cells of the seminiferous tubules have been implicated; available evidence favors the former site.

The liver is the main site of catabolism of testosterone and of the conjugation of its known metabolites with glucuronic or

mouse units per day Gonadotropin is not detectable in the urine of normal children before the onset of puberty HPG is absent or diminished in hypogonadism secondary to pituitary or hypothalamic disturbances and frequently in chronic debilitating diseases malnutrition and starvation The excretion of HPG is increased in many but not all primary testicular disorders In general elevated levels appear to be related to the degree of damage to the seminiferous tubules

**Testicular Biopsy** This procedure is of great value in the diagnosis and prognosis of testicular disorders It provides information concerning both the gametogenic and endocrine functions of the testis—the status of the seminiferous tubules and the Leydig cells Biopsy examination of the testis is of use in differentiation of primary and secondary testicular failure in determination of the specific nature of the testicular defect and its prognosis and in distinguishing azoospermia due to obstruction in the passage of sperm from that due to other causes Preferably a specimen should be obtained from each testis

**Examination of Semen** Specimens of semen for analysis are usually obtained after an interval of 3 days following the last ejaculation The volume of the specimen the number of sperm per ml and the motility and morphology of the sperm are determined

**Determination of the Sex Chromatin Pattern** Chromosomal sex can be indirectly assessed by cytological methods because of a sexual dimorphism in the nuclear structure of somatic cells first described by Barr et al Preparations suitable for examination can be obtained from smears of buccal mucosa skin biopsy specimens or blood This test is widely used in the investigation of abnormalities of sex differentiation including males with defective testes and azoospermia or severe oligospermia When a female chromatin pattern is detected in a phenotypic male with bilateral testes the test is indicative of a primary testicular disorder congenital in nature (see Klinefelter's syndrome, seminiferous tubule dysgenesis)

**Response to Chorionic Gonadotropin** The effects of human chorionic gonadotropin (HCG) on the immature testis are similar to those of LH It induces differentiation and growth of Leydig cells and the secretion of androgen and estrogen The clinical response to HCG has been used as an assay aid in differentiating between primary and secondary hypogonadism

## Pubertal Development in the Male

There are wide variations in the age of onset duration and the sequence of events which characterize the biological pattern of male puberty In normal boys signs of puberty may appear at any age between ten and seventeen years the average age of onset is twelve to thirteen years Once initiated the major changes are usually completed or well advanced in three to four years in a small percentage of normal persons adult maturity is not attained until the age of twenty one

A substantial body of evidence suggests that the stimulus for release of pituitary gonadotropin at puberty originates in the hypothalamus and is mediated by a neurohumoral secretion It seems likely that a certain level of physiological maturation presumably including the central nervous system is necessary before this complex and incompletely understood mechanism is activated This level of development is best reflected by the degree of osseous and epiphyseal development (bone age) rather than the chronological age

The sequence of events which marks the pubertal period is initiated by an acceleration in the growth of the testes and scrotum The initial increase in testicular size is largely attributable to changes in the seminiferous tubules which occupy more than 90 per cent of the mass of the testis This phenomenon has suggested to some workers that secretion of FSH precedes that of LH Following the initial acceleration of testicular growth there is an increase in the size of the penis the appearance of pubic hair which has at first a transverse growth gradual enlargement of the prostate and other accessory organs and glands and areolar and subareolar enlargement of the breast

Concomitantly usually between the ages of thirteen and fifteen a marked acceleration of growth takes place involving primarily the skeleton and muscles More subtle changes occur elsewhere The adolescent growth spurt is completed in about three years and in boys accounts for an average increment in height of about 8 inches (4 to 12 inches) and a gain in weight of about 40 pounds Much has been written about the behavioral changes and the psychosexual dynamics of the adolescent period the reader is referred elsewhere for a discussion of this subject

It is necessary that the physician be cognizant of the wide range of normality in the pubertal process in the time of onset

[illegible]

are detectable in urine. In adult men (and women) there is a gradual fall with advancing age in the amount of 17 ketosteroids and androgen excreted a fall which begins during the third decade. The excretion of 17 ketosteroids does not necessarily reflect biological activity determined by animal assay although the results tend to parallel one another. For example in men with advanced Addison's disease 17 ketosteroid excretion is markedly diminished but there is only about a 50 per cent reduction in androgen excretion. On the other hand in castrate men the diminution in urinary androgen is relatively greater than the decrease in 17 ketosteroids. The excretion of 17 ketosteroids is generally reduced in eunuchoidism. However the values obtained in such patients may fall within the normal range or occasionally may even reach the upper limits of normal. In panhypopituitarism the function of both the testis and the adrenal cortex is impaired and the level of urinary 17 ketosteroids is greatly decreased. Low values are also frequently obtained in chronic debilitating diseases and renal insufficiency.

**Determination of Urinary Estrogen** It has recently been suggested by Maddock and

Nelson that the increase in urinary estrogen following the administration of chorionic gonadotropin (a placental gonadotropin with luteinizing properties) is a more precise and sensitive index of Leydig cell function than the determination of either 17 ketosteroid or androgen excretion. Unfortunately at present there is no simple relatively specific chemical method for this determination in urine.

**Determination of Urinary Gonadotropin**  
Gonadotropic substances in the urine of normal men and nonpregnant women have been designated in the past as urinary FSH. However, since the urinary concentrate as prepared for routine bioassay contains a mixture of pituitary gonadotropins, Albert has suggested the term HPG (human pituitary gonadotropin). The ratio of FSH to LH in the human male hypophysis is about 1:1. On the other hand, male urinary gonadotropin contains relatively more FSH than LH. The excretion of gonadotropin (HPG) is not uniform and spontaneous fluctuations in daily output must be considered in evaluating the results of random determinations. The normal range of HPG excretion by the mouse uterine weight method of Klinefelter and associates is 6 to 52

tion is described as *constitutional* or *idiopathic precocious puberty*. Cerebral lesions particularly tumors accompanied by precocious puberty may affect other hypothalamic functions causing diabetes insipidus, bulimia, obesity, somnolence, emotional lability or disturbances in temperature regulation. Involvement of the optic nerves or visual pathways causes visual disturbances. In some instances signs of puberty precede the onset of detectable neurological involvement and a prolonged period of observation with repeated careful neurological examinations, roentgenograms of the skull and determinations of the visual fields is necessary before it is possible to exclude cerebral neoplasm. In all varieties of true precocious puberty the excretion of urinary 17-keto-steroids rises slowly to normal adolescent values. Initially levels between 2.5 and 4.0 mg per day are usually found. In contrast to precocious pseudopuberty, pituitary gonadotropin (HPG) is excreted in the urine frequently; however, this is not detectable early in the course.

In other forms of isosexual precocity not related to intracranial causes, the testes remain more or less immature. In contrast to the enlarged phallus, and true puberty does not occur. Accordingly, this type has been called *incomplete sexual precocity* or *precocious pseudopuberty*.

The commonest cause of *incomplete sexual precocity* in boys is adrenocortical hyperfunction due to congenital virilizing adrenal hyperplasia or a virilizing adrenocortical tumor. This is also the commonest cause of isosexual precocity in males. With few exceptions the testes remain prepubertal in size despite enlargement of the penis and scrotum and development of other secondary sexual characteristics. An ectopic nodule of hyperplastic adrenal tissue is occasionally palpable in the testis and may be confused with Leydig cell tumor. The excretion of 17-ketosteroids is profoundly increased in relation to chronological age and in adrenal hyperplasia an excessive amount of urinary pregnanetriol is detectable (see section on Adrenal Disorders).

Interstitial cell tumor of the testis is an exceedingly rare cause of isosexual precocity. In all but two of twenty-three reported cases the tumor was unilateral and the contralateral testis was immature. Gynecomastia was present in three patients. The excretion of 17-ketosteroids varied from 3 to 64 mg per day.

Iatrogenic sexual precocity has been pro-

duced by the administration of male sex hormone and is seen not infrequently in boys who have been treated with large doses of chorionic gonadotropin for cryptorchidism.

## Hypogonadism

Testicular insufficiency or hypogonadism is used herein in its broader sense to denote a deficiency of either or both the endocrine and gametogenic functions of the testis. Depending upon the nature of the physiological defect, hypogonadism can be divided into two groups: (1) Hypogonadism secondary to a deficiency of pituitary gonadotropins involving a lack of LH or more commonly both LH and FSH; (2) Hypogonadism of primary testicular origin. The latter includes disorders characterized by small testes androgen deficiency and absent or low HPG excretion. (2) Hypogonadism of primary testicular origin includes disorders accompanied by normal or increased levels of urinary gonadotropin and a variable degree of androgenic function from normal to deficient. Of common occurrence are primary lesions of the testis involving only spermatogenic function which result in infertility. On the other hand, when androgenic function is deficient usually but not invariably spermatogenesis is impaired.

**Androgen Deficiency.** The clinical signs and effects of androgen deficiency depend upon the age of onset—prepubertal, pubertal or postpubertal—and upon the severity and duration of the deficiency.

Total loss of testicular androgenic function usually secondary to surgical castration, atrophy or congenital defects of the testes before the onset or at an early stage of puberty results in eunuchism in adulthood. Hamilton has studied such patients in detail. Prepubertal castration is associated with disproportionate growth of the skeleton produced by the delay in epiphyseal closure. The span exceeds the measurement for height by several inches and the distance between the symphysis pubis and the sole (lower segment) measures more than 55 per cent of the height. Tall stature is common but not invariable. (The characteristic skeletal proportions of the eunuch are not pathognomonic and may be found in otherwise normal men.) The shoulders tend to be narrow and although the habitus may be lean or obese, excessive fat deposition often occurs about the pectoral region.

intensity and duration and also of normal variations in the degree of development of the secondary sex characters. In normal men the pitch of the voice the size of the external genitalia the amount of body hair and the body habitus all vary from individual to individual and are largely attributable to genetic factors and not to differences in the secretion of testosterone.

**Delayed Adolescence** Commonly failure to undergo sexual maturation by the average age is ascribable to an idiopathic normal variation in pubertal development. Puberty occurs spontaneously usually by the age of sixteen years but occasionally even later. Delayed adolescence although inherently a benign condition is often a severe psychological handicap to the patient and a cause of much anxiety to his parents. Many of these boys are short and a delay of several years in osseous development is not uncommon. Not infrequently there is a history of late onset of puberty in other members of the family.

In addition to idiopathic delay in sexual maturation or pubertal failure or arrest in pubertal development secondary to gonadal or pituitary disease retardation of puberty may be due to inadequate dietary intake and to chronic debilitating illness since these may be associated with diminished secretion of pituitary gonadotropin. A rare cause of delayed puberty is previously unsuspected hypothyroidism.

**Disorders involving the pituitary hypophysis** or testes must be excluded in instances of delayed puberty. Roentgenographic examination of the skull and careful examination of the fundi and visual fields are required as well as search for other signs of neurological involvement in all boys who are significantly delayed in their sexual development particularly if this is accompanied by stunting of growth. It may be advisable to assess other pituitary functions. The diagnosis of hypopituitarism is difficult to establish in this age group in the absence of a demonstrable lesion in the region of the hypophysis. A therapeutic trial with chorionic gonadotropin or testosterone may be of value. In boys with delayed adolescence sexual maturation frequently continues after the cessation of hormone therapy however in pituitary hypogonadism the induced changes regress.

**Treatment** If a cause of the delayed adolescence is found treatment should be directed toward correction of the basic disturbance (e.g., measures to improve nutrition surgical removal or irradiation of a pituitary neoplasm). If a lesion involving

the hypophysis or testes is detected it is advisable to institute substitution therapy with male sex hormone at about thirteen or fourteen years of age so that the onset of the patient's own puberty coincides with that of his coevals. Less well defined is the treatment of boys in whom no apparent etiological factor is found. Many will mature spontaneously before seventeen years of age and merely represent an extreme of the normal range. Indiscriminate use of hormonal treatment in this group is unwise and a conservative approach is indicated. Nonetheless at times psychological considerations may make it expedient to treat such boys. A therapeutic trial with human gonadotropin 500 to 1000 IU three times weekly injected intramuscularly or with a testosterone preparation for three to four months frequently initiates the physiological reactions of puberty and maturation will progress after treatment is discontinued.

## Sexual Precocity

**Isosexual precocity** in boys is defined as the occurrence of signs of masculinization before the age of ten years. Skeletal maturation is accelerated and the epiphyses fuse at a premature age leading to short stature in adult life. On the other hand mental and dental development are not precocious. Sexual precocity occurs about three times more frequently in girls than in boys. The main causes of isosexual precocity in boys can be divided into three groups: cerebral, adrenocortical and testicular.

The cerebral causes of sexual precocity may be functional or organic. They are associated with premature activation of the hypothalamic-pituitary mechanism and the release of pituitary gonadotropic hormones. This form commonly designated *true precocious puberty* or *complete isosexual precocity* is manifested by maturation of the testes and spermatogenesis.

*Precocious puberty* may be caused by organic lesions of the brain either directly or indirectly involving the posterior hypothalamus such as hypothalamic and pineal tumors, craniopharyngioma, hydrocephalus, postencephalitic lesions, congenital defects, tuberous sclerosis and neurofibromatosis. The McCune-Albright syndrome of sexual precocity, polyostotic fibrous dysplasia and pigmented areas of skin is rare in boys. Where no organic cause is found the condi-

**Treatment** The testicular lesion is irreversible. If androgen deficiency is present treatment with male sex hormone is effective. The gynecomastia is not affected by hormonal treatment and mastectomy may be necessary in some patients for cosmetic reasons.

**Germinal Aplasia** This condition is characterized by seminiferous tubules lined with Sertoli cells, little or no tubular fibrosis, and absent or rare germinal cells. Leydig cell function is usually normal. Azoospermia is an invariable finding. The testes are normal or moderately reduced in size. Urinary gonadotropin may be increased or normal. The sex chromatin pattern was male in fifteen out of sixteen patients reported in one study. Although it has been suspected that in most instances germinal aplasia is a developmental defect, the lesion has also been described following exposure of the testis to ionizing radiation in which case it may be reversible and in some cryptorchid testes.

The histopathology and the clinical findings in patients with congenital defects of the testis (testicular dysgenesis) are highly variable. Gonadal dysgenesis (in chromosomal males) and male pseudohermaphroditism, which are discussed on pages 758 and 759, are other forms of testicular dysgenesis.

**Anorchia** Absence of both testes in phenotypic males is exceedingly rare. Careful surgical exploration is required to establish the diagnosis. Unilateral anorchia is more common and may result from testicular atrophy following herniorrhaphy or at attempted orchiopexy or from a developmental disturbance in which case other anomalies of the genitourinary tract are not uncommon.

**Infertility** In a variety of testicular lesions the defect involves only spermatogenic function and results in infertility. Endocrine manifestations are absent. Either the semen lacks sperm or the number or quality of sperm is impaired. Testicular biopsy has assumed a major role in differentiating the various disturbances in spermatogenic activity and in determining prognosis. Azoospermia is usually associated with severe tubular fibrosis, germinal aplasia, or spermatogenic arrests and oligospermia with germinal cell desquamation, hypospermatogenesis, incomplete spermatogenic arrest, and less severe forms of tubular fibrosis. In most cases the etiology is unknown. Azoospermia may also result from obstruction in the excurrent ducts secondary to gonor-

rhea, tuberculosis, or a nonspecific infection.

Sterility is a common sequel of bilateral cryptorchidism, being an almost invariable result of thermal injury to the germinal cells if the testes are not brought into the scrotum before puberty is well advanced. It may follow orchitis caused by mumps, brucellosis, leprosy, or occasionally some other severe systemic infection. It may result from x-ray and other irradiation of the testes, or it may be of developmental origin as in seminiferous tubule dysgenesis. MacLeod has shown that even relatively minor illnesses may be accompanied by a profound depression in sperm count. Starvation and chronic debilitating diseases associated with inanition adversely affect spermatogenic function. Estrogen and large amounts of testosterone will also suppress spermatogenesis.

**Treatment of Infertility in the Male** Although important advances have been made in the evaluation of spermatogenic function, treatment of the infertile male is in general both difficult and unsatisfactory. Only rarely is it possible to correct the underlying cause. The results of therapy of inherent testicular defects in spermatogenesis in noneunuchoidal men by the use of large doses of androgenic steroids, gonadotropins, pregnenolone, thyroid, and vitamin preparations have been notably unsuccessful and for all purposes negligible. Although testosterone in massive dosage depresses spermatogenesis, intermittent treatment with relatively small doses may be of value in some patients with oligospermia. Harvey and Jackson have attributed the beneficial effect to more efficient ejaculation and to improvement in the quality of the semen.

## SECONDARY HYPOGONADISM

Secondary hypogonadism is due to pituitary gonadotropic failure which may result from neoplastic, inflammatory, traumatic, vascular, and degenerative lesions involving the hypophysis or hypothalamus, such as pituitary adenoma, craniopharyngioma, astrocytoma, infarction, carotid aneurysm, granulomas, especially tuberculosis, and histiocytosis (Hand-Christian disease and eosinophilic granuloma), hemochromatosis, idiopathic atrophy, and developmental defects. In many instances, including the idiopathic and familial forms, the nature of the underlying lesion is not known. A functional and reversible depression of gonadotropic activity occurs in malnutrition, in

the hips thighs and lower abdomen Muscular development is poor and strength is impaired Except for the appearance of sparse pubic hair secondary sex characters fail to appear and the voice remains juvenile True gynecomastia is commonly present The skin exhibits a characteristic fine wrinkling about the face especially in the perioral and periorbital regions a generalized pale and sallow appearance and increased distensibility Acne and baldness do not occur Sex drive and potentia are absent or markedly reduced The basal metabolic rate is lower in many instances than in normal men In some cases there is anemia usually of a mild degree The erythrocyte sedimentation rate characteristically rises after castration

The effects on somatic and sexual development of partial loss of testicular androgenic function are less striking and vary greatly in degree Characteristic of the milder forms of eunuchoidism are the scant growth of facial hair and a female distribution of pubic hair In men who have attained sexual maturity castration does not result in complete regression of secondary sexual characteristics and the signs of androgen deficiency are less conspicuous The commonest signs are reduction in prostatic size diminished growth of the beard and body hair the appearance of fine wrinkles around the eyes and a pasty sallow complexion Semen volume is reduced Potentia and libido though usually diminished frequently persist Vasomotor phenomena including hot flushes occur occasionally

### PRIMARY HYPOGONADISM

(Primary Failure of the Testis)

The problem of classification of primary hypogonadism has not been entirely resolved mainly because the etiology of many of the disorders in this group is uncertain Primary hypogonadism may result from genetic and developmental defects thermal injury as in cryptorchidism trauma destruction and degeneration following orchitis or exposure to ionizing radiation neoplasm and surgical castration Disorders in this group may or may not be accompanied by androgen deficiency although in some eunuchoidism is a constant or frequent feature The excretion of gonadotropin (HPG) is normal or increased depending apparently upon the integrity of the seminiferous tubules

Klinefelter's Syndrome, Seminiferous Tubule Dysgenesis This syndrome described

in 1942 by Klinefelter Reifenstein and Albright and later modified by others has recently been a subject of considerable interest and re-evaluation The characteristic features which become apparent during or after puberty include a variable degree of eunuchoidism azoospermia gynecomastia and small testes with atrophy and hyalinization of the seminiferous tubules in which Leydig cells are preserved In most instances the cause is an early developmental defect of the gonad in others the syndrome may be associated with a postnatal lesion

The discovery that some individuals with this syndrome have a female chromatin pattern has served to identify those cases due to anomalous development of the gonad In accordance with this observation and the histopathological characteristics of the testicular lesion the term *seminiferous tubule dysgenesis* has been suggested for this group This affliction is a common cause of primary hypogonadism Of twenty-nine patients studied by Grumbach Blanc and Engle nineteen had a female chromatin pattern Although seminiferous tubule dysgenesis may occur in phenotypic males with either female or male nuclei in many instances the cause of Klinefelter's syndrome with a male chromatin pattern is uncertain

The only constant clinical features of seminiferous tubule dysgenesis are infertility and the small size of the testes which are often firmer than normal in most instances testicular atrophy is severe Gynecomastia and eunuchoidism are variable features and when present first appear during the pubertal period Hypospadias and cryptorchidism have been observed infrequently Mental retardation is not uncommon This disorder has also been reported in association with myotonia dystrophica

The excretion of urinary gonadotropin is usually but not invariably increased In general urinary 17 ketosteroids are within the normal range

Although the etiology of seminiferous tubule dysgenesis has not been established the occurrence of this affliction in families and in identical twins favors genetic predisposition as a factor It has been postulated that in the chromosomal females the defect results in failure of the cortical component of the primordial gonad to develop and to suppress the medullary component (Fig 85) As a consequence the gonad chromosomally destined to become an ovary differentiates as a testis albeit a defective one

## Treatment of Androgen Deficiency

The most useful substances for the treatment of androgen deficiency are the preparations of testosterone which are available in forms suitable for intramuscular oral and buccal or sublingual administration or as pellets for subcutaneous implantation. The mode of administration depends for the most part on the preference of the patient and the cost.

Esterification of testosterone with organic acids potentiates its activity when injected as an oily solution. Testosterone propionate in doses of 25 to 50 mg by intramuscular injection twice or three times weekly is usually adequate for replacement therapy. However longer acting esters are available which can be administered less frequently. One dose of 200 to 400 mg of testosterone cyclopentylpropionate or testosterone enanthate is highly effective when injected at three to four week intervals.

Methyltestosterone is an effective preparation for oral and buccal or sublingual use. It is usually administered in doses of 50 mg (30 to 75 mg) per day orally or about 25 mg per day by sublingual absorption. It is not a natural compound and its metabolism differs from that of testosterone. Administration of the 17 methylated derivative does not cause an increase in 17 ketosteroid excretion in addition although a potent anabolic steroid it frequently produces creatinuria rather than retention of creatine.

Pellets of testosterone implanted subcutaneously provide an efficient and economical method of administration. Implantation of 750 to 1000 mg usually suffices for four to six months. However patients usually prefer one of the slowly absorbed intramuscular preparations when a sustained androgenic effect is desirable.

No potent protein anabolic steroid lacking androgenic properties in man is available at present although intensive efforts have been made to obtain one.

**Undesirable Effects.** These include edema due to retention of extracellular electrolyte (an uncommon effect except with use of large doses or in elderly persons with diminished cardiac reserve), acne, gynecomastia, depression of spermatogenesis in some fertile men when administered in large doses, masculinization in women and premature closure of the epiphyses. Rarely methyltestosterone causes intrahepatic cholestatic jaundice.

Androgen therapy is contraindicated in patients with carcinoma of the prostate.

## Cryptorchidism

The terms "cryptorchidism" and "undescended testes" are used synonymously to designate testes which have never descended into the scrotum. Unilateral cryptorchidism is approximately four times as common as bilaterally undescended testes. A cryptorchid testis may be situated in the abdomen within the inguinal canal or in an ectopic position outside the scrotum and the normal pathway of descent. The majority of undescended testes are inguinal. To avoid needless treatment it is essential to distinguish this condition from *migratory* or *retractile testes* which lie in the lower or upper scrotum and with the slightest stimulus are withdrawn into the inguinal region and occasionally into the abdomen by contraction of the cremasteric muscles.

The testes usually descend into the scrotum at about the eighth fetal month. Occasionally descent is delayed until or shortly after birth. Incomplete descent is common in premature male infants. Scorer found undescended testes at birth in 3.4 per cent of 1500 full term male infants. During the first month of life 50 per cent of the undescended testes reached the scrotum. In a prospective study of the incidence of congenital anomalies by McIntosh and associates only 0.5 per cent of 2793 live born male infants had undescended testes at 12 months of age. The incidence of unilateral and bilateral cryptorchidism in large series of adult males has been variously estimated at 0.2 to 0.4 per cent. Spontaneous descent occurs frequently during the first year of life. It is probably less common after this age than was previously supposed.

The etiology is incompletely understood. Maldescent may be due to mechanical abnormalities which deter the passage of an otherwise normal testis or to imperfect development of the testis attributable to an inherent testicular defect or to a deficiency of gonadotropin. Recent studies indicate that testicular dysgenesis is an important etiological factor. In rare instances unilateral or bilateral cryptorchidism is the only anatomical abnormality of the external genitalia in individuals with intersexuality.

**Diagnosis.** The most difficult aspect of diagnosis is distinguishing the true unde-

chronic disease states associated with inanition and nutritional deficiencies and in some patients with myxedema. High concentrations of androgen as in the adrenogenital syndrome may cause secondary hypogonadism. Excess estrogen either from ingestion or from an endogenous source such as a feminizing adrenal tumor depresses the secretion of pituitary gonadotropin. The testicular atrophy and gynecomastia which occur in some patients with severe liver disease have been ascribed by some to increased levels of estrogen due to impaired hepatic degradation of these steroids. Irrespective of etiology, in almost all instances of secondary hypogonadism urinary gonadotropin is absent or markedly diminished.

The deficiency of pituitary gonadotropic function occurs either as an isolated defect (hypogonadotropic eunuchoidism, pituitary hypogonadism) or in association with a deficiency of other hormones of the anterior pituitary (hypopituitarism). On the other hand, hypoadrenalism or hypothyroidism secondary to pituitary failure rarely is found without concurrent involvement of gonadotropic function and secondary hypogonadism. In some instances only the secretion of LH is impaired. Albert et al have termed this partial gonadotropic failure. In any event, secondary hypogonadism is always accompanied by inadequate androgenic function of the testes and with rare exceptions, absent or deficient spermatogenesis.

The clinical manifestations vary with age of onset, degree of the deficiency, and whether there is coexistent deficiency of other anterior pituitary hormones. Hypopituitarism occurring during childhood commonly designated pituitary dwarfism results in proportionate dwarfism and complete sexual infantilism. The characteristic features of prepubertal or pubertal gonadotropic failure (hypogonadotropic eunuchoidism) occurring as a selective pituitary deficiency include a eunuchoid habitus, small testes, lack of development of secondary sexual characteristics, absence of urinary gonadotropin, and low 17-ketosteroid excretion. The absence of gynecomastia, regarded by some as a salient feature, is of doubtful clinical value in differentiating primary from secondary hypogonadism. Deposition of fat in the pectoral region is common and at times may be difficult to distinguish from true gynecomastia. Isolated pituitary hypogonadism is relatively rare in adult men; more frequent occur-

rence is a variable degree of panhypopituitarism (see section on Pituitary Diseases).

It is essential in all instances to obtain roentgenograms of the sella turcica and to plot the visual fields. Testicular biopsy is useful but considerable experience is necessary for adequate interpretation. When hypogonadism is accompanied by adrenal insufficiency, the excretion of 17-ketosteroids is usually less than 3.0 mg per day at a level significantly below that found in castrate men. As previously emphasized, urinary gonadotropin is absent (less than 6 mouse units).

McCullagh and his associates were the first to describe a group of eunuchoid men with relatively intact spermatogenic function whom they termed *fertile eunuchs*. The size of the testes were normal or only moderately reduced. Leydig cells were absent or hypoplastic and androgen deficiency was always present. Urinary gonadotropin (largely FSH) was excreted in normal but not increased amounts. Some cases appear to be due to a selective deficiency of LH; in others the primary defect may be testicular in origin. The response to chorionic gonadotropin has been variable. Similar findings have been reported by Albert in a patient with arrest of puberty caused by a pituitary tumor.

The pathogenesis of testicular atrophy which follows traumatic injury to the spinal cord is uncertain. Both primary and secondary hypogonadism have been described in the Lawrence-Moon-Biedl syndrome.

**Treatment.** A physiological approach to the treatment of secondary hypogonadism necessitates the use of gonadotropin therapy. Unfortunately, FSH preparations derived from animal sources are not consistently effective and when repeatedly injected stimulate immunological mechanisms which reduce the hormone's effect. Chorionic gonadotropin, obtained for commercial use from human pregnancy urine, stimulates the Leydig cells to secrete androgen but must be administered at frequent intervals (three to four times a week). It does not have a direct effect on the seminiferous tubules, although in a few instances of partial gonadotropic failure, spermatogenic as well as Leydig cell function improved after its use. Because long continued administration of chorionic gonadotropin is expensive and in general impractical, substitution therapy with a testosterone preparation is usually advisable and effectively corrects the deficiency of androgen.

from prolonged stimulation by chorionic gonadotropin. To minimize this risk Robinson and Engle recommend a short intensive course of 4000 units of chorionic gonadotropin administered intramuscularly daily for three days. Hormonal treatment is contraindicated when the testis is ectopic or associated with a hernia.

If the undescended testis is atrophic and biopsy examination at the time of surgery shows irreversible changes it is generally advisable to perform orchiectomy provided the contralateral testis is in the scrotum. This also applies to a testis which despite all attempts at mobilization cannot be brought into the scrotum.

### Impotence

Impotence is a complicated problem which may be either relative or complete and may involve any phase of the sexual act. Although it is a symptom of androgen deficiency and of genitourinary or neurological disease in many instances it is psychic in origin. When impotence is the principal complaint of a patient it is usually the result of an emotional disturbance in which case androgen therapy is valueless and at times may add to the psychic trauma. Ganglion blocking agents as used in the therapy of hypertension are also a notable cause of impotence.

### Male Climacteric

The spontaneous occurrence of a male climacteric is still controversial. Although in women during the fifth decade ovarian failure and a compensatory rise in gonadotropin excretion is an anticipated and physiological accompaniment of the aging process, spontaneous testicular deficiency of sufficient degree to produce symptoms is an exceedingly rare occurrence. Many of the symptoms ascribed to this syndrome are common in psychoneurotic syndromes in middle aged and elderly men. The diagnosis should be documented by finding an increased excretion of gonadotropin and by testicular biopsy and confirmed by obtaining a therapeutic response to androgen therapy but not to placebos.

### Orchitis

*Acute orchitis* a common complication of mumps is a rare occurrence in the course of other specific infectious diseases. Mumps orchitis infrequent before puberty occurs in 18 to 43 per cent of cases of mumps in postpubertal males usually five to seven days after the onset of parotitis. Involvement of the salivary glands is not invariably present. Testicular involvement is bilateral in about 20 per cent of cases of mumps orchitis. The orchitis is manifested by high fever and a swollen tense painful exquisitely tender testis. Concurrent epididymitis is common. The acute symptoms usually persist for three to four days; the orchitis in general subsides in seven to ten days. As a result of inflammation and edema of the testis conspicuous atrophy occurs in about 50 per cent of the cases and sterility in an undetermined number of instances. In treatment of mumps orchitis cortisone and related steroids have been used in large doses with encouraging results. Symptomatic relief has been prompt in most instances but the effect of corticosteroid therapy on the incidence of testicular atrophy and infertility remains to be determined.

*Chronic orchitis* is associated with painless hard sometimes nodular enlargement of the testis. Syphilis the most common cause may produce an interstitial orchitis in which the testis is characteristically smooth and wooden in consistency ("bilhard ball" testis). Involvement is frequently bilateral. Other causes include tuberculosis, leprosy, brucellosis, glanders and certain parasitic infections such as filariasis and bilharziasis.

### Tumors of Testis

*Tumors of the testis* are uncommon comprising about 2 per cent of all forms of cancer in the male and frequently are malignant. The greatest incidence occurs in the third and fourth decades. Testicular tumors may arise from any of the cellular components of the testis or their embryonal precursors.

Considerable uncertainty applies to classification especially of those new growths whose origin has been ascribed to the potentially totipotent germ cell. Melnikow has suggested the following classification

scended testis from the more common retractile testis of childhood repeated examinations may be necessary especially in obese boys. It is important to ascertain by careful inquiry whether the testis at any time has been observed in the scrotum. In cryptorchidism the homolateral side of the scrotum is empty and poorly developed. The patient should be carefully examined in the erect and recumbent positions in a warm room and with warm hands. Bimanual examination and palpation while the patient performs the Valsalva maneuver or while the examiner applies pressure to the lower abdomen are useful procedures. In boys with retractile testes elicitation of the cremasteric reflex often results in a localized puckering of the scrotal skin. If the testis is palpated in the normal pathway of descent gentle manipulation should be used in an attempt to displace it into the scrotum. Such mobile testes do not require therapy and will remain in the scrotum with the advent of puberty. Failure to palpate a testis on multiple occasions suggests that the testis is intra-abdominal, atrophic or absent. However spontaneous descent may subsequently occur even in instances in which the testis is not felt.

**Treatment.** The treatment of undescended testes is a vexing and controversial subject. Experienced observers differ in their approach to the problem. Though opinions are strong there are too many gaps in our knowledge to justify dogmatism. Major considerations are (1) the potential fertility of the undescended testis, (2) the likelihood of spontaneous descent and (3) the propensity of the undescended testis to undergo malignant change.

It is well established that during or after puberty the undescended testis shows degenerative changes which eventually proceed to atrophy. With good reason these changes have been ascribed to the deleterious effect of the higher temperature of an extrascrotal environment on the testis especially on the germinal epithelium. The tubules gradually undergo progressive fibrosis and loss of germinal elements although androgenic function may persist for many years. Almost all men with bilateral undescended testes are sterile. However general agreement is lacking as to the age at which the fertility potential of the cryptorchid testis is impaired. Although Nelson and Robinson and Engle and others have observed a lag in development of the seminiferous tubules and in some instances a mild degree of fibrosis in testes retained

after the age of six to ten years the significance of these changes is uncertain after puberty irreversible degenerative changes frequently take place.

The incidence of cancer in undescended testes is considerably greater than in scrotal testes and more so in abdominal than in inguinal testes. Although precise statistics are not available the overall risk appears to be small with the exception of the dysgenetic frequently undescended gonads of intersexes which are especially prone to malignant degeneration.

The most important problem in the treatment of patients with cryptorchidism is the age at which it is advisable to attempt correction. Treatment consists of orchiopexy or of the administration of chorionic gonadotropin followed by orchiopexy when necessary. It is generally agreed that therapy must be instituted before puberty is advanced if irreparable testicular damage is to be prevented but opinions differ in regard to the optimal age for treatment. In the more common unilateral cryptorchid the scrotal testis if normal is adequate for fertility. Treatment is recommended for cosmetic reasons to facilitate examination for neoplasm and as additional insurance against infertility in the event the scrotal testis is defective or impaired at a later age. In bilateral cryptorchidism preservation of fertility is the major consideration. Here the risk of damage to the testis by orchiopexy which even in experienced hands is not negligible must be weighed against the possibility of infertility if surgical treatment is delayed too long. When bilateral orchiopexy is followed by atrophy of the testes the patient will be eunuchoid as well as sterile. Since the majority of undescended testes descend before puberty the writer believes it is justifiable to delay treatment until nine to eleven years of age unless the testis is ectopic or associated with a hernia.

Many workers recommend a course of treatment with chorionic gonadotropin before orchiopexy. In some cases hormonal therapy is effective and orchiopexy is unnecessary. It is the opinion of most that testes which descend with such therapy would have descended spontaneously at puberty under the stimulus of endogenous gonadotropin. Testes which fail to descend are either inherently defective or mechanically retained. Some experienced workers are of the view that hormonal treatment should not be used for long periods because of the possibility of damage to the testis.

dates when the gonads are ovaries and true hermaphrodites when both ovarian and testicular tissue are present. The application of nuclear tests of chromosomal sex has brought to light two additional forms of intersexuality namely gonadal dysgenesis in chromosomal males and seminiferous tubule dysgenesis (Klinefelter's syndrome) in chromosomal females. In both instances the gonads are defective or absent and there is discordance between chromosomal sex as determined by nuclear morphology and somatic sexual development (phenotypic sex). Persons with postnatal virilization or feminization or with psychiatric disorders such as homosexuality are not included among abnormalities of sex differentiation.

Anomalies of sex are not exceedingly rare and may result from genetic defects or from deleterious environmental factors. In many forms the etiology is still uncertain.

The syndrome of gonadal dysgenesis (ovarian agenesis, Turner's syndrome, Bonneville-Ullrich syndrome) is manifested in its typical form by female but infantile development of the accessory sex structures including the external genitalia, short stature, a characteristic habitus and multiple congenital defects. The most common associated anomalies include webbed neck, coarctation of the aorta, lymphedema of the extremities and ocular, skeletal and renal defects. No true gonad is present as such; in each mesosalpinx there is a ridge of connective tissue devoid of ova follicles or seminiferous tubules. Except for the development of some pubic and axillary hair (in contrast to hypopituitary dwarfs) no secondary sexual development occurs and these patients remain sexually infantile. The titer of urinary gonadotropin is increased but rarely before nine years of age. A male chromatin pattern has been found in about 80 per cent of patients with this syndrome and is of diagnostic significance. A number of variant forms have been described; rarely the clitoris is enlarged. Therapy is directed toward the cor-

rection of sexual infantilism (see Disorders of Ovary) and remediable congenital anomalies.

*Seminiferous tubule dysgenesis* is discussed on page 752.

The management of patients with ambisexual development is greatly facilitated by early diagnosis. Infants with anomalous development of the external genitalia deserve prompt investigation. The reader is referred to the publications of Wilkins, Money, Hampson, Grumbach and others for detailed discussions of diagnostic therapeutic and theoretical considerations and for additional references.

## Diseases of the Female Gonads

The human ovary has a dual physiological responsibility: (1) the development and production of ova and (2) the elaboration of at least two hormones, estrogen and progesterone, and probably a third hormone, relaxin.

The time of greatest ovarian activity is

between the menarche and the menopause. Activity before the menarche or after the menopause and lack or aberration of activity between these events represent pathological ovarian function. This may be due to (1) abnormal stimulation of the ovary by other glands, (2) end organ disease, (3)

## A Primary tumors

## I Germinal

1 Pure seminoma

2 Embryonal tumors

a Embryoma

b Choriocarcinoma

c Embryonal carcinoma

d Teratocarcinoma

e Adult teratoma

3 Combinations of 1 and 2 and of the various types of embryonal tumors

## II Nongerminal tumors

1 Interstitial cell tumor

2 Sertoli cell tumor

3 Tumors of testicular stroma  
fibroma lipoma etc

## II Secondary tumors

I Lymphoma plasmacytoma leukemia  
etc

## II Metastatic carcinoma

**Germinal Tumors** Most common are germinal tumors and of these *seminoma* exceeds in frequency all other testicular tumors. *Seminoma* although usually fairly uniform in cellular architecture may contain embryonal elements such as chorionic syncytium in the primary growth or in metastatic lesions. In contrast to the embryonal tumors which tend to invade the spermatic cord and to metastasize early especially to lung seminomas in general are relatively slow growing and commonly invade the iliac and periaortic lymph nodes before generalized dissemination is demonstrable. In addition seminomas are frequently highly radiosensitive whereas embryonal tumors are usually resistant to radiotherapy. The significantly increased incidence of germinal tumors particularly seminoma in undescended testes and in the dysgenetic gonads of intersexes has been discussed above.

Many patients with germinal tumors excrete increased amounts of urinary gonadotropin. The gonadotropin may be pituitary in origin (HPG) and may show principally FSH activity on bioassay or it may originate from tumor tissue in which event chorionic gonadotropin (HCG) is detectable in the urine. Increased excretion of HPG is usually found in association with seminoma. The significance of this association is not clear but it may reflect the increased incidence of this tumor in patients with certain inherent testicular defects. Excretion of chorionic gonadotropin is most frequently associated with embryonal tumors especially choriocarcinoma. However neither increased levels of HPG nor detectable amounts of HCG are consistently found in patients with germinal tumors even when the involvement is widespread nor is one type of gonadotropin

invariably associated with either seminoma or the embryonal tumors.

**Interstitial Cell Tumors** Tumors of this type are rare occur at any age and are usually but not invariably benign. In boys interstitial cell tumors cause sexual precocity but not true puberty since spermatogenesis is absent. Their only recognizable endocrine manifestation in the adult is gynecomastia which has been observed in about 10 per cent of cases.

**Clinical Symptoms and Signs** The most common and characteristic symptom is painless and frequently rapid enlargement of the testis. The swelling is firm diffuse and symmetrical in most instances but may be nodular. Occasionally there is dull dragging inguinal pain and rarely flank pain which has been attributed to involvement of the periaortic lymph nodes. Attachment of the testis to the scrotal skin is rare. The iliac inguinal and femoral lymph nodes may be enlarged. Metastasis to a deep cervical node is sometimes found. Occasionally tumors of the testis are associated with a coincident hydrocele. Gynecomastia may occur with germinal or interstitial cell tumors.

Tumor must be differentiated from tuberculosis from syphilitic orchitis from other forms of acute and chronic epididymo orchitis and from hydrocele spermatocele and adenomatoid tumor of the epididymis.

**Management** The treatment is surgical removal of the involved testis and depending upon the nature of the tumor radical resection of regional lymph nodes and irradiation. The five year survival rate for seminoma is greater than 75 per cent. The mortality rate is high for other germinal tumors with the exception of adult teratoma.

## Hermaphroditism

## (Intersexuality)

These terms are commonly used to designate a group of congenital abnormalities characterized by a variable degree of ambisexual differentiation of the accessory sexual structures and gonads of one or both sexes. Intersexes may be further subdivided depending upon the sex of the gonad into male pseudohermaphrodites when the gonads are testes female pseudohermaphro-

Should investigation and possible exploration prove entirely negative it must be assumed that the child has developed a physiological sexual cycle at an earlier than normal age and that no treatment is possible or necessary.

From a physiological point of view precocious puberty of this type is apparently harmless. A number of cases followed by Novak throughout their active sexual years proved to be normally reproductive and became menopausal at a normal age.

Emotionally and socially however children of this type present a serious problem because they are not only distinctly different from their contemporaries but also not sufficiently mature emotionally to cope with the sexual drive which inevitably results from estrogen production. That they are actually reproductive at this age has been demonstrated many times (75 primipara under thirteen years of age were reported from the University of Arkansas Medical Center for instance) but possibly most dramatically by the now famous case of Lena Medina, the Peruvian girl who was delivered of a normal child by cesarean section at the age of five years and eight months. Sections of the ovaries taken at the time of cesarean section disclosed old corpora lutea and corpora albicantia which indicated that she had been ovulating for a considerable length of time.

Parenthetically in this era when estrogen tablets are not infrequently found in the family medicine chest it should be observed that the age-old tendency of children to experiment with pill swallowing has resulted in the occurrence of precocious uterine bleeding as a result of exogenous estrogen stimulation. Cases of this type seen by the author as well as those reported by Cook and others have not however had evidence of the development of other secondary sex characteristics and their episodes of vaginal bleeding have been very irregular and sporadic.

The other possible abnormality of the menarche, i.e. delayed onset of menstruation is much more frequent and its etiological factor or factors more difficult to identify and treat.

Apprehension concerning delayed menarche is more often expressed by mothers than by the patients themselves and it is most important to carry out a thorough history, physical examination and laboratory investigation before stating to the mother and daughter that this is merely a physiological delay. Aside from the usual routine of history taking, emphasis should be

placed on ascertaining when other secondary sex characteristics developed on whether the patient has ever had any systemic ailments and on a careful inquiry into the patient's emotional, environmental and familial status.

In order to eliminate the possibility of congenital abnormality of the female genital tract as an etiological factor it is most important to carry out a thorough examination of the external genitalia followed by a vaginal examination or should the condition of the hymen not permit it a careful rectal examination. Not infrequently girls in their late teens who subsequently have been found to have some developmental abnormality of the genital tract which has made menstruation for them impossible have been extensively treated with hormone therapy in attempts to bring on menstruation.

These congenital abnormalities may occur anywhere along the genital tract. A rare but significant developmental abnormality is complete fusion of the hymeneal ring which prevents egress of menstrual fluid even though the patient may be going through cyclic episodes of uterine bleeding. This process produces hematocolpos and hematometra which occasionally reach such proportions that the uterus can be easily palpated suprapubically and also produces periodic episodes of fairly severe lower abdominal discomfort and cramps at the time when the patient is actually having occult menstruation. This condition is easily identified by local examination. Incision under local or general anesthesia results in a satisfactory cure.

Absence of the uterus in the presence of intact ovaries is also rare. It is identified not only by physical examination but also by the presence of other secondary sex characteristics whereas congenital absence of the ovary with or without the presence of the uterus has as one of its characteristics no indication of sexual development of any kind. Occasionally cases of ovarian agenesis are seen however with a moderate amount of breast development and pubic and axillary hair growth. This evidence of estrogen activity probably results either from estrogen produced by the adrenal or from exogenous estrogen which the patient has received therapeutically elsewhere but of which she is unaware. In all cases of suspected ovarian agenesis at least two separate twenty-four hour urine specimens should be obtained for a determination of urinary gonadotrophin excretion. A high or "menopausal" level of uri-

ovarian disease or neoplasm or (4) systemic pathology

Evidence of ovarian function is provided by observation of the development and activity of secondary sex organs such as the breast and the internal and external genitalia. Ovarian hormone production develops the latent existing characteristics of femaleness and combined with ovum production provides the organism with the essential characteristics of being a female. Both of these essential ovarian processes are triggered by gonadotrophin secretion from the pituitary gland. Under normal circumstances ovarian hormone activity is probably most graphically expressed in the periodic phenomenon of menstruation.

Therefore any abnormality of secondary sex development or physiological function represents either a pathological organ or a pathological stimulus. The ovary may be normal but may receive abnormal hormonal stimulus or none at all or its own normal hormonal secretion may be ineffective because a pathological condition of the target organ prevents the latter from being receptive. With this in mind the causes of aberrations of ovarian function in different age groups can be reasonably identified by a systematic search using available diagnostic techniques for the offending unit in the hormonal chain. Once the source of the difficulty is identified and only at this time can the patient be rationally treated.

### Menarche

The menarche or onset of menstrual function in the human occurs with greatest frequency at the age of twelve or thirteen but there is a wide latitude in the time of its physiological onset. When menstruation begins before the age of ten or after the age of fifteen a decision must be made whether the precocious or delayed menarche is a physiological variant or whether it is due to some anatomical, glandular or systemic abnormality.

Cases of precocious menstruation even at the age of three or four have been reported by Novak in which no pathological abnormalities could be identified either hormonally or surgically although rare and bizarre diseases may be etiologic factors. Idiopathic precocious menstruation however is almost invariably accompanied by other secondary sex characteristics and is a condition naturally suspected of accumulat-

ing estrogen from an abnormal source. Possible abnormal sources of estrogen production are functioning tumors of the ovary or adrenal or some abnormal pituitary stimulus. Novak found that over 90 per cent of his cases were idiopathic or physiological.

Such conditions must be searched for by rectal examination under anesthesia, laboratory assay of adrenal function and sella turcica x ray. Since estrogen production is obvious it need neither be searched for nor measured but the difference between the hormonal activity of a functioning ovarian tumor and a normal but precociously stimulated ovary can sometimes be identified by determining the presence or absence of ovulation. If the precocious menstruation has any degree of regularity a twenty four hour urine specimen may be obtained premenstrually for pregnandiol determination. Should this excretion product of progesterone be present it is an indication that ovulation has occurred a phenomenon which would not be present in the presence of a functioning ovarian tumor. This is therefore a good indication that the ovary is precociously stimulated by gonadotrophin either from a pituitary tumor or because the process of growth in the individual has proceeded so rapidly that the pituitary gland has started its gonadotrophic function several years sooner than usual. Other means for determining ovulation such as endometrial biopsy and basal body temperature are not considered practical in this age group. It must be remembered that the absence of evidence of ovulation does not necessarily mean the presence of a functioning ovarian tumor because an ovary especially at the time of the menarche may be sufficiently stimulated to produce estrogen but not to ovulate.

Surprisingly small tumors of the ovary may produce sufficiently large amounts of estrogen to accomplish secondary sex development and function. Therefore unless the examiner is reasonably sure that rectal examination under anesthesia discloses no ovarian enlargement surgical exploration of the pelvis should be carried out.

Cortical hyperplasia or tumor of the adrenal which may cause precocious menstruation is usually accompanied by other signs of aberrant sexual development such as hirsutism and a search for abnormal steroid excretion should be instituted. Pituitary tumors which produce precocious menstruation may also have other local or systemic symptomatology (q v) as well as abnormal x ray findings.

the patient actual evidence that it is possible for her to menstruate. There is a possibility that the pituitary and subsequent ovarian depression produced by estrogen administration may result in a physiological rebound phenomenon following therapy resulting in a surge of gonadotrophin production and subsequent spontaneous menstrual activity but this is purely theoretical.

## Ovarian Abnormalities During Active Menstrual Life

Probably the most delicate and certainly the most frequent indicator of aberration in ovarian function is the occurrence of some change in the menstrual process. Although alterations in the occurrence, frequency, amount and length of menstrual bleeding may be caused by many types of local or systemic pathology, it is nevertheless true that ovarian dysfunction has as its most sensitive "ovimeter" changes in menstrual function which may be called dysmenstruation\* (if we may be allowed to coin a generic word to represent any type of menstrual abnormality)\*.

The ovary of course is subject to a variety of disorders—infectious, neoplastic, degenerative, possibly metabolic—but this section is mainly concerned with the hormonal physiology and pathology of the ovary. Various types of ovarian tumors also produce ovarian hormonal malfunction, and for a thorough discussion of this type of ovarian abnormality the reader is re-

\*An expression used for the same purpose by Buxton and Southam, *Human Infertility*, New York: Paul H. Hoeber Inc. 1958.

ferred to the recent extensive monograph by Morris and Scully.

Dysmenstruation thought to be due to ovarian hormonal abnormalities is classified under various names. By some these are considered to be "functional" menstrual disorders, the implication presumably being that they occur in the absence of any recognizable local or systemic pathological conditions and are therefore not "organic." Others prefer to call these disorders "dysfunctional," the implication being that normal menstruation is "functional" and therefore any abnormality in menstruation should be considered dysfunctional. Regardless of the semantics involved, the present discussion concerns hormonal aberrations of ovarian function of which dysmenstruation is the most frequent symptom. Other symptoms of ovarian hormonal malfunction may be obesity, hirsutism, vasomotor instability and infertility, but if these symptoms are in fact due to ovarian endocrine disease, they are also accompanied by menstrual aberrations.

Therefore, when a patient complains of any sort of dysmenstruation, an effort must be made to determine whether this symptom is due to ovarian dysfunction or whether it has some other physiological or pathological cause. Although dysmenstruation is an almost invariable indicator of ovarian dysfunction, it must not be assumed that this is the only cause. Therefore, before any treatment is instituted, other causative factors must be considered and ruled out by a process of elimination. A possibly oversimplified check list for this process might be similar to that listed below.

Such a simple check list does not take into account the rare situations in which endometrial carcinoma may occur coinci-

### Symptom—Amenorrhea

#### Cause—Physiological

Before menarche  
After menopause  
Pregnancy  
Lactation  
Absence of one or more genital organs

#### Congenital

#### Psychological or

#### Pathological

Systemic disease including thyroid or adrenal disease

### Symptom—Menorrhagia and Metrorrhagia

#### Cause—Local disease

Neoplastic—benign or malignant—carcinoma of cervix or corpus  
polyps, adenomyomata, fibromyomata, etc.  
Trophoblastic abnormalities—any pregnancy abnormalities which cause bleeding

Inflammatory reactions—vagina, cervix, uterus, tubes, ovaries, pelvis in general

#### Systemic disease

Blood dyscrasias, chronic debilitating disease, thyroid or adrenal abnormalities

#### Psychiatric

nary gonadotrophin excretion is an indication of either complete absence of ovarian tissue or ovarian tissue which has been so destroyed by some pathological change that it is unresponsive to gonadotrophin stimulation

In the event that no congenital abnormalities are identified and the investigator is reasonably certain that ovarian tissue is present thorough physical and laboratory examination must be carried out to eliminate the possibility of abnormalities of other endocrine glands or of systemic disease. The presence of masculinizing characteristics such as hirsutism, unusual development of skeletal musculature or voice changes leads one to suspect the presence of functioning ovarian, adrenal or pituitary tumor or of adrenal cortical hyperplasia. These conditions will be discussed in subsequent paragraphs.

Chronic systemic disease, infectious, metabolic or neoplastic, may prevent the onset of menstruation just as it may produce secondary amenorrhea in later life and any such condition must be carefully searched for. List but by no means least among the etiological possibilities for late onset of the menarche are emotional and environmental factors which in this sensitive psychosexual area may be subtle and difficult to identify. Intolerable conscious or subconscious personal and environmental conflicts may have their somatic manifestation in a repudiation of sexuality as such and menstruation is certainly one of the most obvious manifestations of the femaleness which is being repudiated. The hormonal physiology of menstruation is so delicate and cortical-hypothalamic-hypophyseal-ovarian-endometrial relationships so intimate and complex that a stimulus initiated in the cortex may well find its response in endometrial inactivity.

Should no local or systemic abnormalities be found and the patient deemed to be in a reasonably stable emotional state (which in an adolescent permits considerable latitude!) the patient and her mother should be reassured concerning her menstrual status with the information that (1) this is a not infrequent and normal physiological variant and (2) the late onset of the menarche in no way compromises reproductive function in the future. She should be told that after all the only physiological usefulness for the menstrual cycle is a preparation for reproduction and that since she does not under ordinary circumstances wish to reproduce at this age, menstruation

is actually physiologically unnecessary for her.

It may be psychologically necessary however because the girl may have a not unreasonable feeling of being an abnormal person unless she menstruates the way her contemporaries do. Furthermore for some unknown reason the mother of such a child is frequently most insistent that some effort be made to bring on the menarche and no amount of rational explanation will overcome this emotional fixation.

Under these circumstances there is no reason why a few artificial menstrual cycles produced by exogenous estrogen should not be used as a valid therapeutic procedure. This may be carried out by the administration of 3 to 5 mg. of diethylstilbestrol daily by mouth for 20 days following which a period of estrogen withdrawal bleeding will occur within five to ten days thus convincing the patient and her mother that she can in fact menstruate. This may be repeated for two or three cycles followed by a period of therapeutic rest to find whether or not this artificial hormonal stimulus has in some way triggered the patient's hormonal mechanism so that cyclic menstruation results. Should the latter not occur a few induced periods per year should not be harmful but prolonged and excessive administration during teenage years especially should be avoided because such therapy depresses pituitary gonadotrophin activity. The spontaneous onset of normal menstruation has certainly been known to occur as late as the eighteenth or nineteenth year and excessive previous hormone therapy may only further delay the already delayed maturity.

Diethylstilbestrol occasionally produces nausea and even vomiting in which case some other orally administered estrogen may be used. The reason for using stilbestrol first is that this synthetic compound is much less expensive than natural estrogens but if it is found desirable to use the latter conjugated equine estrogens in amounts of 3.75 mg. daily for 20 days may be used ethinyl estradiol in amounts of 0.5 mg. is also satisfactory. These substances are administered orally.

It must be remembered that this type of therapy does not stimulate the ovary. It is in fact a replacement for ovarian function. It not only does not produce but actually depresses ovulation and may well depress ovarian hormone production also. Therefore the main function of this therapy is really a psychological one — to present to

such is actually the menopause. Therefore when the cessation of menstruation occurs physiologically because of primary ovarian failure at the conventional menopausal age therapy is rarely necessary (see subsequent paragraphs). On the other hand there are unusual and as yet but little understood cases of primary ovarian failure in younger women. The expression "menopause praecox" or premature menopause has been conventionally and incorrectly used for many years to describe and identify secondary amenorrhea whatever the cause in young women. This expression should be used only for those patients who have been proved to have acquired primary ovarian failure before the age of forty. To qualify for such a diagnosis a young woman must fulfill the following requirements: (1) secondary amenorrhea (2) consistently high FSH excretion at menopause levels (3) vaginal smear or endometrial biopsy showing no estrogenic activity (4) actually observed ovaries (either by culdoscopy or laparotomy) which are atrophic and senile in appearance. Patients of this type usually appear with a chief complaint of secondary amenorrhea, fairly severe hot flushes and various subjective symptoms such as depression, nervousness, loss of libido, etc. The cause of this extraordinary premature ovarian senility is completely unknown and fortunately the condition is not common. No satisfactory treatment of this condition exists at the present time except substitution therapy with estrogen in the minimal amount which will relieve the patient of distressing symptoms. Stilbestrol 0.2 to 0.5 mg. per day is usually sufficient for this purpose. As has been mentioned, complete or partial cessation of ovarian function may be due to a cessation of gonadotrophic stimulus from the pituitary. Although the symptoms of this type of indirect ovarian failure may be somewhat the same, the treatment is quite different and therefore it is important to identify this kind of case. Gonadotrophin activity of the pituitary may be determined by the examination of a twenty-four hour urine specimen for FSH content. This test is done by most adequately equipped biological laboratories and may be considered more accurate and satisfactory than most other biological assays. FSH output by the pituitary under normally functioning hormonal conditions varies from a few mouse units to 30 or 40. Excessive excretion of FSH of over 100 mouse units per twenty-four hour specimen is generally considered to be a menopausal level because it indicates that the hypophy-

sis is free from any estrogenic inhibiting effect. Under ordinary circumstances the amount of estrogen secreted by the normal ovary inhibits gonadotrophin secretion by the pituitary gland. The continued complete absence of FSH excretion indicates the presence of either some definite pituitary pathology or some unsuspected psychiatric factor inhibiting hypothalamic-pituitary stimulation. Thus the treatment of this type of patient rests not in attempts to provide ovarian steroid substitution therapy but in attempts to identify and treat the pituitary pathology which has resulted in gonadotrophin failure. Occasional cases of chromophobe adenomas of the pituitary for instance develop amenorrhea as the first clinical symptom.

Not infrequently cases of partial pituitary ovarian failure are seen which are represented by menstrual irregularities and occasional anovulation. Partial ovarian failure is represented hormonally either by variations in the amount of ovarian steroid excreted or by variations in cyclic function. Again for the most part the clinical evidence of these ovarian aberrations is a change in menstrual function varying from amenorrhea to menometrorrhagia. It is quite apparent that in order to produce estrogen during the first two weeks of the menstrual cycle and estrogen plus progesterone during the latter two weeks the ovary must go through a process of ovulation at about the middle of a twenty-eight day cycle (Actually regardless of the length of the menstrual cycle ovulation if it occurs at all almost always occurs fourteen days before the next expected period). If ovulation does not occur no corpus luteum is formed by the ruptured graafian follicle and no progesterone is produced. Cyclic bleeding may occur however even in the absence of ovulation; this is known as anovulatory bleeding or anovulatory menstruation. Since in the absence of progesterone no progestational changes occur in the endometrium, bleeding develops from endometrium of a purely proliferative (estrogenic) type and although this type of menstrual bleeding may be clinically indistinguishable from the bleeding which occurs from progestational or secretory endometrium, it not infrequently is abnormal in amount and the period itself may be unduly prolonged.

The anovulatory cycle is identified by premenstrual curettage or endometrial biopsy and need not be treated unless the patient is an infertility problem or menstruation is so profuse or prolonged that

**Table 1 The Characteristic Hormonal Abnormalities in Cases of Amenorrhea (Assuming that Local Systemic or Psychiatric Causes Have Been Eliminated)**

	GONADOTROPHINS	ESTROGENS	ENDOMETRIUM	OVARY	17 KS
Pituitary inadequacy	0	0	Atrophic	Inactive	Normal or low
Primary ovarian failure (ovarian agenesis or menopause)	++++	0	Atrophic	Atrophic	Normal
Endometrial failure (rare)	+ or ++	++++	None	Normal	Normal
Hyperhormonal amenorrhea	+ or ++	++++	Hyperplastic	Normal with no corpora lutea	Normal
Polycystic ovary	? or + or +++++	Variable	Variable	Multiple follicular cysts	Normal
Adrenal cortical hyperplasia or tumor	+	Minimal	Variable	Atrophic Grossly normal Polycystic	Elevated
Thyroid disease	+	Minimal	Variable	Normal	Low in myxedema

dentally with amenorrhea for instance nor does it emphasize enough the fact that either no menstruation or profuse menstruation may have the same etiological factors. With limitations like these in mind however they may be used as a satisfactory framework for the identification of organic or psychiatric pathology other than hormonal.

If the investigator has proved to his own satisfaction that none of the conditions cited exists in the patient who complains of one of these symptoms he may then assume that the hormonal function of the ovary is unsatisfactory either because the ovary is incapable of producing its appropriate steroids estrogen and progesterone or that it is not being properly stimulated to do so by gonadotrophins from the pituitary. With these possibilities in mind the investigation of the hormonal causes of dysmenstruation becomes somewhat easier. Table 1 may help to explain the technique by which any of these abnormalities should be investigated. An attempt has been made to provide means of identification for all the gradations of ovarian activity from ovarian agenesis (and therefore no activity) to normal ovulation (and therefore normal cyclic ovarian function). This diagnostic process of seeking to identify, accuse and convict the guilty gland involves certain specific tests for further information concerning which the reader is referred to the monograph by Escamilla.

#### THERAPY OF INADEQUATE HORMONAL FUNCTION OF THE OVARY

The therapy of inadequate ovarian hormonal function depends not only on the degree of hormonal failure but also on the

therapeutic objective which the physician desires to obtain for his patient. Although not a luxury, certainly menstruation is not a necessity except in the infertile patient; therefore except in the treatment of infertility and possibly in rare psychological situations a patient need not be treated purely for the purpose of recreating menstrual cycles. On the other hand certain patients who show other evidence of estrogen deficiency such as loss of other secondary sex characteristics certainly need and deserve either substitution or stimulative therapy.

The patient with ovarian agenesis (or more properly gonadal dysgenesis) for instance should be given exogenous estrogen therapy not to make her menstruate but to provide her with the secondary sex characteristics which will transform her from a sexually completely undeveloped individual into a synthetic female. Once this type of congenital abnormality is recognized the therapy consists of cyclic estrogen administration. Five mg of diethylstilbestrol is administered daily for three weeks. A decreasing dosage is resumed at the onset of withdrawal bleeding which usually occurs five to ten days following the interruption of therapy. A gradual decrease in dosage is then continued until a minimum level is reached which will develop and maintain the patient's secondary sex characteristics. Estrogen administration may be continued indefinitely in this fashion. If the patient is nauseated by stilbestrol other oral estrogens as previously described may be administered.

The ovary which is present but nonfunctional presents a somewhat different therapeutic problem. Primary ovarian failure as

## The Menopause

Since the menopause is the clinical manifestation of the cessation of ovarian function it is appropriate that this physiological condition be considered in the section on the female gonad. It is important to remember however that the menopause is a physiological and not a pathological phenomenon. It is not a disease but a normal representation of normal primary ovarian failure. Menstruation ceases for various other reasons at various other times of life but in middle age when the ovary becomes senile and atrophic and ceases to respond to gonadotrophic stimulation it will no longer fulfill its two basic functions of egg and sex hormone production. At this time the woman experiences irrevocable evidence of the process of aging. The human female is probably the only menstruating primate who ceases to menstruate at about middle age. This might be considered a sign of evolutionary progress because it is possibly unwise genetically emotionally and physiologically for the human female to produce offspring after middle age. Therefore since the menstrual process is no longer useful nature has provided a technique whereby it ceases.

Sometime between the ages of forty and fifty-five the ovary undergoes gradual or rapid regressive atrophy which results in a great variety of clinical changes mostly represented by gradually diminishing menstrual function. In some cases there is a gradual decline in estrogen production over a fairly long time—in fact possibly as long as two or three years. In others the ovaries cease this activity quite abruptly thus a woman who has had very adequate estrogen production may very quickly within a period of a month or two experience practically complete cessation of ovarian function. In some women the ovaries may revitalize themselves periodically their activity may almost cease only to recur briefly in declining amounts until after a year or two no evidence of further estrogen production can be found.

The menopause as such then may occur fairly suddenly or it may drag itself out over a period of a year or more. Ultimately however not only are no more eggs produced but so far as we know there is very little if any sex hormone production. No amount of gonadotrophin stimulation can produce activity in the menopausal ovary and even though the hypophysis secretes large amounts of gonadotrophin postmenopausally—in fact because it is

released from estrogen depressive action possibly more even than during actual menstrual life—the ovary does not use it and it is excreted in large amounts in the urine. Measurement of gonadotrophin in the urine is one of the methods of diagnosing the physiological condition of the menopause when it is important to differentiate it from possible pathological amenorrhea.

There is considerable controversy at the present time concerning the activity of the postmenopausal ovary. Certain investigators believe that the postmenopausal ovary continues to carry out some kind of hormonal function albeit at a much more modest level than during active menstrual life and there is some evidence that this may possibly be true in some women. On the other hand it is extremely difficult to demonstrate physiologically any evidence of estrogen production by the postmenopausal ovary. The psychological implications of the menopause and of surgical castration by oophorectomy are so profound in the human female that subjective evidence of ovarian function postmenopausally or postcastration is most undependable. Objective evidence of minimal estrogen production may be obtained by observation of the vaginal smear or possibly of endometrium obtained from endometrial biopsy but even if evidence of minimal estrogen activity is present it is not proof that the postmenopausal ovary is the source of this steroid because estrogen is not only produced by the adrenal but is also ingested in various amounts from various different kinds of food. Even potato contains estrogenic substance and at the present time meat and poultry are likely to contain synthetic estrogenic substances as a residue from estrogen administration to cattle and poultry for the purpose of tenderizing meat and producing hormonal caponization.

What however are the clinical symptoms of this process of ovarian aging when the rest of the woman may be active healthy and vital physically emotionally and mentally? So far as we know at the present time the only symptoms which have actually been proved to occur as a result of sudden or possibly even gradual ovarian deficiency are the symptoms of vasomotor instability such as hot flushes and possibly transitory dizziness and head aches.

There in addition to the amenorrhea which has provided this condition with its name are the only symptoms which in any way have been proved to result from estrogen depletion. An extraordinary num-

some kind of therapy is considered advisable. In the latter case proliferative endometrium may be changed to a progestational or secretory variety during the latter two weeks of the cycle by the administration of progesterone or progesterone-like compounds. By thus developing a mature premenstrual endometrium and permitting bleeding to occur from it normal menstruation results and the patient is relieved of the profuse and prolonged blood loss which previously occurred. Until recently the most satisfactory technique of progesterone therapy was the intramuscular injection of 10 mg. of progesterone daily for about ten days. There are now available however synthetic progesterone-like steroids commonly called 19-Nor compounds which produce striking progestational effects when administered by mouth. The dosage of these substances has not as yet been accurately worked out but they also are administered for about ten days premenstrually in order to produce a satisfactory secretory endometrium.

The anovulatory cycle in the infertile patient is quite another problem because the absence of ovum production not the menstrual abnormality is the critical factor. Since anovulation very probably represents inadequate or aberrant pituitary-ovarian relationships the theoretical treatment of anovulation should be administration of the appropriate gonadotrophin. At the present time however this is impossible for two reasons. The first is that there is still considerable ignorance concerning the exact type and amount of gonadotrophin (or gonadotrophins) which is (are) secreted at various times in the menstrual cycle and the second is that no gonadotrophin is available therapeutically which has the characteristic of stimulating the primate ovary to ovulation. Hopeful advances in this direction have been made by Van Wagenen and Simpson who have produced numerous ovulations in the primate (Rhesus) by the administration of Rhesus pituitary extracts. Such is the species specificity of gonadotrophin that it is hoped that whereas equine, bovine or sheep pituitary extracts have failed to stimulate the human pituitary in the past possibly primate pituitary extracts will have a more satisfactory effect in the future.

Much has been written concerning the use of so-called therapeutic radiation of the anovulatory ovary in attempts to produce ovulation. There is reasonably good evidence that ovarian irradiation (in amounts of about 200 r over the pelvis)

has some effect on the ovary which occasionally causes it to ovulate. Whether this radiation produces a depression of an inhibitory substance (estrogen?) on hypothalamic gonadotrophin secretion or whether its action is mediated otherwise is unknown. It must be emphasized however that this type of therapy has great genetic danger because of the possibility of producing chromosomal mutations which may result in genetic abnormalities in subsequent generations. Therapy of this type is therefore considered inadvisable.

The cyclic nature of menstruation with its ebb and flow of gonadotrophin and ovarian steroids is such that any hormonal imbalance may alter not only menstrual function but also the actual physiological condition of the ovary. Occasionally as a result of causes unknown cyclic function ceases and the ovary as though freed from some governing influence persistently and continuously secretes estrogen without any tidal variation in amount or unaccompanied by progesterone production. This results in estrogenic hyperplasia of the endometrium with a temporary period of amenorrhea followed by profuse and severe endometrial bleeding. Such a condition is identified by curettage which also occasionally has a therapeutic effect but under these circumstances the same sort of progestational therapy as previously mentioned for the anovulatory cycle should be carried out.

Another type of cyclic malfunction probably again due to some dislocation of pituitary-ovarian hormonal relationships is the development of the polycystic ovary. This condition produces amenorrhea and is not infrequently accompanied by obesity and hirsutism; therefore great care must be taken to differentiate this condition from adrenal cortical hyperplasia or the presence of a functioning adrenal tumor (qv). Bilateral polycystic ovaries are usually identifiable on pelvic examination because this type of ovary is two or three times normal size but it is sometimes advisable to carry out culdoscopy to verify this diagnosis. The only cure for this condition known at the present time is bilateral ovarian wedge resection accomplishing the removal of about one third of each ovary. The percentage of cures following such a procedure with subsequent ovulation and normal menstruation is surprisingly high being somewhere in the region of 80 per cent. The reason why such a surgical procedure cures this condition so often is at present unknown.

estrogen replacement until the age when the menopause would probably be expected.

Viewing the menopause from this stand point then how can we most efficiently and successfully care for the patients who consult us for advice and help during this time of life? Again it must be stressed that no kind of therapy should be undertaken until a thorough investigation is made by history physical examination and necessary laboratory work. If no organic disease is found it may be said that therapy could be divided into three categories: psychological, hormonal and medical.

It is hoped that the foregoing discussion has sufficiently emphasized the fact that many symptoms attributed to the menopause are actually due to the psychological stresses which occur at this time of life. Frequently these stresses involving adjustments to physical status, environment, family and friends are due to inadequate knowledge and understanding of the physiological process through which the patient is going. Because there are such common lay misconceptions concerning the menopause it is frequently necessary not only to disabuse patients of strange and bizarre ideas but also to educate them. Emphasis on the naturalness and innocuous characteristics of the menopause is frequently of considerable help for patients who are confused. The simple psychotherapy of dissemination of knowledge with sympathetic understanding should always be adequate for helping patients through this time of life. Occasionally however profound depression accompanies the menopause in the form of involutional melancholia or even paranoid states. These patients have almost always had a previous history of psychiatric instability which the additional strain of the climacteric brings into focus. They are therefore more psychiatric problems than menopausal and should be placed under psychiatric care.

Nonspecific medical therapy for the menopause should be carried out before resorting to the tempting expedient of using estrogen substitution therapy. Mild barbiturate administration greatly helps a patient in her necessary readjustment to herself and to her environment. The recent surge of enthusiasm for "tranquilizing" drugs has resulted in a complete new appendix to our pharmacopoeia. Undoubtedly many of these are worthwhile in ameliorating the psychological problems arising at this time of life and their judicious and careful use may be of great assistance to the physician. The type and amount of

tranquilizing drug must depend on the resourcefulness and experience of the physician but it is quite apparent that what may be a most satisfactory type of therapy in one patient is not adapted to another nor are these medications a substitute for helping the patient to achieve what might be called endogenous rather than exogenous tranquility and equanimity.

In the event that medical therapy has been unsuccessful especially in the relief of hot flushes produced by vasomotor instability hormonal therapy for the menopause is legitimate and necessary. It must be remembered however that aside from the cessation of menstruation vasomotor instability is actually the only immediately recognizable change in this physiological process. Therefore hormonal substitution therapy should not be engaged in unless the patient's symptoms are thought to result from this vascular change. There are many types and varieties of available estrogen both naturally occurring and synthetic. Whereas conjugated natural estrogen was at one time almost universally administered by intramuscular injection this somewhat inconvenient and expensive mode of estrogen therapy is now entirely unnecessary because numerous synthetic and naturally occurring estrogens are adequately potent when administered by mouth. The writer can think of no situation in which it would be medically advisable to administer estrogen by injection rather than orally. The administration of 0.1 mg. to 0.3 mg. of diethylstilbestrol daily for the relief of hot flushes should certainly be adequate for estrogen replacement therapy. This medication is preferred because it is so inexpensive but if by any chance it produces nausea and vomiting which it does rarely natural estrogen administered by mouth may be substituted in the form of ethynylestradiol in the dosage of 0.05 mg. or sodium estrone sulfate in amounts of 0.625 mg. per day. So far as any physiological measurements of estrogenic activity are concerned there is no identifiable difference in the estrogenic activities of the natural and the synthetic compounds.

It must be remembered that hormone therapy at the time of the menopause since it is replacement therapy actually only postpones the inevitable process of estrogen depletion which every menopausal woman must go through. The rationale for therapy at this time therefore is not to give complete replacement and thereby postpone the inevitable but so gradually to decrease the

ber of other symptoms have been attributed to ovarian failure simply because women occasionally at this time of life have complained of them. Excitability, weeping, palpitation, depression, fatigue, irritability, constipation, dyspnea, sweating and insomnia are but a few of the symptoms for which the menopause is blamed but there has never been any proof whatever that the menopause *per se* or estrogen depletion is responsible for any of this extraordinary galaxy. There is no question that these symptoms do occasionally occur at this time of life and therefore if we do not accuse the menopause as the etiological factor to what may we attribute their origin? If we can answer this we may obtain some appropriate focal point for therapy. There are possibly two sources of these symptoms on which it is worthwhile to comment.

We must be constantly aware of the fact that symptoms of which women complain at this time of life and which are so commonly attributed to the menopause may not actually be symptoms of the menopause at all but of concomitant unrecognized pathological conditions. This is the age during which common degenerative diseases begin to manifest themselves and symptoms of these diseases may be appearing in the guise of menopausal symptoms while the real etiological factor is lurking in the background. Women suffering from hypertension, diabetes, hyperthyroidism, even brain tumors and many other common or bizarre diseases the symptoms of which have simulated exactly those frequently attributed to the menopause are all too frequently treated by estrogen substitution therapy because they are erroneously thought to be suffering from ovarian failure. It is therefore extremely important to investigate every patient during this stage of life who has incidentally ceased to menstruate in order to avoid the misfortune of later being presented with irrevocable evidence of a full-blown degenerative disease the process of which might have been retarded had it been recognized earlier.

The other possible source of the many symptoms described above is of course the psychological change which occurs at this time of life and which the menopause brings into focus. The menopause is the irrevocable physical expression of the process of aging. It brings irresistibly to a woman's mind that she has fulfilled her reproductive physiological usefulness that she is no longer young and that she must

readjust her approach to life. A frequent topic since Old Testament times the involuntal psychoses of the menopause are today a favorite item for psychiatrists and specialists in psychosomatic medicine. Individuals acquire somatic symptoms because of the attitudes toward the menopause which their education and background and emotional life have led them to develop. It is a time of life when psychological stability is frequently difficult to sustain and women in these decades develop unnecessary fears and apprehensions concerning themselves, their environment and their relationship to their families and friends. Add to these factors the additional folklore and gossip concerning the alleged misfortunes of the menopause and it is really not surprising that women suffer from all sorts of subjective complaints at this time of life. It is quite apparent that the unfortunate symptoms must be treated but it is also quite apparent that they must be treated by techniques other than estrogen replacement as a substitute for ovarian activity. This type of therapy is only a postponement of the inevitable.

This is not to deny completely the fact that there are other pathological changes which occur as a result of estrogen deficiency especially in women who have been deprived of estrogen surgically or by radiation in early age. The possibility that cessation of estrogen production may be an etiological factor in osteoporosis—but certainly not the primary one—is worthy of consideration. Osteoporosis is part of the process of aging but it is undoubtedly aided and abetted by loss of estrogen. We must remember however that this condition occurs in males and also what is probably most important that it is impossible to reverse this process by later administration of estrogen even though a patient may be put into positive calcium balance by estrogen. It is possible that osteoporosis may occur in women who receive exogenous postmenopausal estrogen throughout their postmenopausal years. The occurrence of osteoporosis however in a young woman who has been deprived of ovarian function either surgically or radiologically is an entirely different matter. This woman really has physiological need of estrogen because of the pathological deprivation of this hormone at an age when it is supposed to be physiologically present. Therefore in order to reproduce the characteristics of this age group in terms of estrogen production it is most certainly advisable to carry out

## DISEASES OF THE THYMUS GLAND

Many possible functions have been attributed to the thymus gland but thus far none has been subject to proof. Classic extirpation experiments in a variety of animals have given no conclusive results. Extracts of many types have been tested but the results have been variable. The planning of such experiments is exceedingly difficult because of the fact that in our ignorance of the functions of the thymus the conditions for making any effects recognizable have not been fulfilled. There are certain clinical relationships which suggest that the thymus has an endocrine function. Myasthenia gravis is associated in many instances with a tumor of the thymus. In many cases of hyperthyroidism a disease associated with thymic enlargement muscular weakness is a prominent feature and the occasional development of myasthenia gravis in association with exophthalmic goiter is probably more than coincidental. In a number of reported cases a thymoma has been associated with depressed erythrocytogenesis and anemia relieved following thymectomy. Much discussion has taken place about the relationship of thymus enlargement to sudden death in infants particularly during anesthesia. The function of this organ and its relationships to clinical disease are still for the most part shrouded in mystery.

**Anatomy and Physiology** In the normal thymus of infants there is a well defined cortex consisting of closely packed masses of cells ("thymocytes") resembling lymphocytes and a medulla. During the process of differentiation into cortex and medulla concentric masses of cells the Hassall corpuscles appear in the sheets of epithelial cells of the medulla. Opinion varies as to the nature of the thymocytes. Some observers contend that the thymocytes are in reality lymphocytes and appear in the gland only after invasion from without. Others believe that the morphologic similarity does not establish their common identity and feel that the cell is formed *in situ* from thymic epithelium.

Near the age of puberty the gland becomes narrower and occupies a relatively

smaller portion of the anterior mediastinum although in actual size it may be larger than in the infant. As involution takes place thymic tissue is replaced by adipose tissue which separates the lobules from each other. The number of lymphocytes in the cortex and medulla decreases but in spite of these changes thymic tissue can with rare exceptions be found in any person regardless of age, type of illness or cause of death. There may be an acceleration of involution brought on by illness, a so called accidental involution. This is probably mediated by the increased adrenal activity in response to stress.

Animal experiments have demonstrated relationships of the thymus to certain of the endocrine glands. Castration and administration of thyroxin in rats cause comparable increases in the weights of the thymus, the lymph nodes and the spleen. Thyroidectomy and treatment with testosterone tend to decrease the weights of these structures. These procedures also prevent the increase in weight of the thymus which follows castration. There is a reciprocal relationship between the size of the adrenal cortex and the thymus. Deficient adrenal cortical secretion results in hypothyroidism and the injection of adrenocortical steroids or the adrenotropic hormone of the pituitary results in a decrease in thymic weight. Rats exposed to low atmospheric pressures for more than two days exhibit an increase in adrenal weight and a significant decrease in the weight of the thymus and testes.

Evidence has been obtained by some investigators of a neuromuscular blocking effect in extracts of thymus and pancreas while others have concluded that extracts of thymus from patients with myasthenia gravis are capable of inhibiting acetylcholine synthesis in contrast to similar preparations from normal individuals. No firm conclusions can be drawn from any of these observations.

**Pathology Atrophy** Nutritional atrophy is a common finding since the thymus involutes rapidly during inanition and febrile illnesses which last for more than a few days. Nine days of starvation in the rabbit

amount of available estrogen that the patient is eased into a state of complete estrogen depletion rather than suddenly thrust into it. We see no necessity for continued estrogen administration over a period of years as is so often practiced and advocated elsewhere. It may be asked why this continued use of exogenous estrogen should not be carried out if the patient so desires and if she thinks it makes her feel better. There are two answers to this question. One is the possibility of carcinogenesis as a result of prolonged and indiscriminate estrogen therapy and the other is the simple fact that it is not a physiological necessity.

That estrogens are carcinogenic in the human female has not as yet been proved. Suspicion has been cast upon this steroid as being a factor not only in uterine and cervical carcinoma but also in mammary carcinoma. Its contribution to carcinogenesis is still speculative. Possibly the most incriminating evidence concerns carcinoma of the endometrium; it has been shown that prolonged uninhibited estrogen production produces a condition of adenomatous hyperplasia which seems almost imperceptibly to pass through an innocuous zone into the area of malignant metaplasia. Therefore, although the status of estrogen as a carcinogenic steroid is at present unclarified, it is nevertheless under suspicion and if it is unnecessary to use this drug are we therefore because of this suspicion justified in using it?

The other reason for not using this drug following the menopause is admittedly a somewhat philosophical one. Nature has arranged matters so that the human female does not need estrogen after the menopause to maintain her mental or physical health, well-being and vitality. Prolonged estrogen administration therefore becomes a specious attempt to turn back the clock and to

assist the patient in escape from reality. Life from the beginning is a process of aging and one aspect of happiness is a mature realization of and acceptance of this fact. If we as physicians aid and abet an escape from reality by trying to help women think they are young when they really aren't, are we actually contributing to their welfare? It is incumbent upon us in every specialty therefore to treat this condition known as the menopause but let us remember that hormonal replacement therapy is one of the minor and temporary aspects of this treatment.

certain instances of sudden death there is no justification for the belief that radiotherapy or extirpation of the thymus would have prevented death. Coe described eight thymic deaths in 2500 operations in children less than eighteen months of age. They were not due to anesthesia or to obstruction of the respiratory tract. The outstanding characteristic was complete absence of respiratory effort and ordinary methods of resuscitation were not beneficial. The heart continued to beat normally after respiration had ceased. He suggested that some curare-like substance might be released under these conditions, an interesting suggestion in view of the possible relationship of the thymus to myasthenia gravis.

**The Thymus and Respiratory Obstruction.** Chronic stridor, attacks of cyanosis and choking in infancy have often been attributed to the thymus. With modern diagnostic methods these symptoms are usually shown to be the result of other causes such as congenital hypotonia of the larynx, congenital obstructive anomalies of the respiratory tract, inflammatory lesions, tetany and other local or general conditions. At the age of six months both the body and the thymus have doubled in weight. The body has tripled in weight by the end of the first year, the thymus not until five years. Thus, after six months to one year the thymus becomes increasingly insignificant as a possible cause of respiratory obstruction. Enlargement of the thymus in the anteroposterior plane is most apt to cause respiratory obstruction and careful roentgenograms in oblique as well as anteroposterior positions are necessary in evaluating it as a factor in any case. Bronchoscopy may show compression and symptoms usually cease after radiation therapy. The diagnosis cannot be made with any certainty by physical examination.

**Irradiation of the Thymus and Carcinoma of the Thyroid.** Irradiation of the mediastinal region in children is not without danger. There is evidence to indicate a relationship between previous irradiation of the chest and the development of carcinoma of the thyroid. It has been observed that one of every thirteen children with carci-

noma of the thyroid has a history of previous irradiation and other studies show that six of every 1400 infants irradiated before fourteen months of age will develop thyroid carcinoma before the age of eighteen years.

**Relationship of the Thymus Gland to Myasthenia Gravis.** (See section on Myasthenia Gravis.)

**Treatment.** The indications for roentgen ray therapy have changed in recent years. "Prophylactic" irradiation to prevent sudden death is not warranted and therapeutic irradiation for respiratory obstruction is indicated only after all other possible causes have been ruled out. Many tumors of the thymus are sensitive to irradiation and remissions have been reported in myasthenia gravis following roentgen therapy. On the whole, however, this form of treatment has not been satisfactory.

Before treatment of a thymic neoplasm a biopsy should be performed for histological diagnosis. Ideal treatment is surgical removal of thymic tumors along with the remainder of the gland. Many authors believe that this should be followed by a full course of irradiation to the mediastinum as the distinction between benign and malignant tumors is difficult histologically as well as grossly. In several reported cases of "benign" tumors, metastases developed two to three years postoperatively. Early excision of all undiagnosed anterior mediastinal masses is advisable and all tumors originating in the thymic area should be regarded as potentially malignant.

will reduce the thymus to 10 per cent of its original size

**Infections** Metastatic abscess formation in the thymus during bacteremia is rare. Tubercles are occasionally found in association with infection of the tracheobronchial nodes. Gummas of the thymus have been reported occasionally.

**Neoplasms** No group of tumors has proved more difficult to interpret and classify than those of the thymus gland. The problems involved are those which have complicated the embryological and histological study of the gland. Because of this lack of specific knowledge of the true histogenesis of the constituents of normal thymus the generic term thymoma has come into use indicating only the primary source of a new growth from thymic parenchyma. A thymoma may originate from thymic lymphocytes, reticular cells, Hassall's bodies or the thymic stroma. Norris feels that the thymomas often associated with cases of myasthenia gravis should be regarded as adenomas produced by an extreme degree of local hyperplasia of the thymic epithelium.

The thymoma is a slowly growing tumor which may arise from both the thymocytic and epithelial cells. The relative proportion of these cellular types varies greatly both in different tumors and in various regions of the same neoplasm. Features commonly present are dense fibrous capsule, distinct fibrous trabeculae, the palisading of epithelial cells about cystic spaces, foci of necrosis, cyst formation and calcification. Most of these tumors lie anterior to the aortic arch and base of the heart but may be located lower. They are usually round or oval, clearly differentiated from the remainder of the gland and may contain sufficient calcium to be seen radiologically. Tumors of the thymus are usually encapsulated but may be adherent to the surrounding organs and invade the pericardium, pleura or lungs. Distant metastasis is rare. The association of a thymoma and agenesis of erythrocytes has been reported in fourteen instances. Myasthenia gravis has been present in only two of these cases. Typically the bone marrow study revealed few or no erythrocyte precursors and myelopoiesis and megakaryocyte activity were usually normal. Thymectomy apparently resulted in relief of anemia in two cases. Improvement in two and failure in two. There seems to be a definite relation between suppression of the erythropoiesis and the presence of a thymoma in these cases.

Myasthenia gravis develops in many patients with benign thymomas. In several instances this disease has appeared a few years after removal of the tumor. Carcinoma of the thymus is a malignant tumor which metastasizes widely, almost never associated with myasthenia gravis.

**Clinical Diagnosis of Thymus Enlargement** Neoplastic enlargement of the thymus of considerable size may occur without the production of any local signs and symptoms. If the enlargement is in the anteroposterior diameter, cough and hoarseness, pain in the chest and neck, dysphagia and compression of the large veins may develop. Pleural and pulmonary involvement with hydrothorax may occur and extension through the chest wall has been described.

Other conditions which must be considered in differential diagnosis are tracheo-bronchial lymphadenitis, mediastinal pleurisy, paravertebral abscess, aneurysm of the aorta and other mediastinal neoplasms.

In the roentgenogram the shadow is more or less circular, sharply defined and located just above the cardiac shadow. Lateral films will show that it occupies the anterior mediastinum. In advanced cases with extension to the pleura and lungs, a circumscribed shadow may not be visible. Other types of mediastinal tumor are likely to be found higher and may occupy the middle and posterior portions of the mediastinum. It is difficult at times to differentiate between a thymoma and an aortic aneurysm.

Because of the great variation in size of the organ in relation to age, physical condition and other factors, there is no satisfactory way of diagnosing diffuse enlargement of the thymus. Some of the tumors are so small that they are not recognized before operation or autopsy and then only by careful search. However, with use of the lateral exposure and tomography, most thymic tumors can be discovered by the roentgenologist.

**Diseases of the Thymus in Infants and Children** *Status Thymolymphaticus* Most of the evidence at present indicates that the state of the thymus and lymphatic structures originally described as enlarged and as associated with the syndrome known as "lymphatic constitution" or *status thymolymphaticus* is in most instances within the limits seen in normally developed persons who have died of a variety of causes. In many of the cases described at autopsy there is adrenal atrophy which is known to be associated with enlargement of the thymus. If such a condition as *status thymolymphaticus* exists and if it is related to

certain instances of sudden death there is no justification for the belief that radio therapy or extirpation of the thymus would have prevented death.
